It is scarcely necessary to say that the brain will as readily feel the application of heat to the shaven head as of cold ; and for the same reason, the woolly-headed negro is perhaps more in need of means to prevent heat from passing from without inwards, than the inhabitants of colder climates are in need of a provision for a contrary purpose. To the bare-headed a plentiful growth of air may be considered a protection against a *coup de soleil* in tropical climates.

We may suppose the whiskers and beard to protect the dental nerve while within its bony canal ; and the frequency of toothache may in some degree be attributed to the natural absence of this covering, or to the practice of shaving. It is certain that

neuralgia attacks most frequently the nerves of the face, these being more exposed to varieties of temperature, from their nearness to the surface, than other nerves. The liability of nerves being affected by exposure to cold is proved by the numerous recorded cases of paralysis of the portio dura of the seventh pair, arising from that cause ; and we may venture to assert, that if the face were allowed to retain its natural clothing of hair, such cases would not be so apt to occur. It would be interesting to ascertain whether nations, as the Turks, who permit the beard and whiskers to luxuriate, are more exempt from toothache, *le douloureux*, paralysis of the seventh pair, &c. than those which are in the habit of shaving. I have the impression that the teeth of Turks are remarkable for their sound condition. It is a prevailing opinion that a tendency to sore-throat is corrected by allowing the hair to grow under the chin.

We may appreciate the benefit to be derived from the sternum being supplied by an extra retainer of heat in the shape of hair, from the fact that travellers exposed to cold often protect the front part of the chest with additional clothing.

The growth of hair on those parts of the abdomen under which lie tissues scantily supplied with blood, as tendon or fascia, would appear more intended to maintain the harmony and consistency of nature, than to confer any effective benefit in supporting the warmth of the abdominal viscera.

It is worth while observing that we often artificially protect those parts which are naturally covered with hair ; there is the rheumatic head and jaws enveloped in flannel ; then there is the coachman, with his chin immersed in his voluminous neck-cloth ; and well he may, for what supply of heat can be expected where there is little else but skin and bone, and where the razor has done its work ? Who has not felt the pain of a cold chin ? Lastly, how often do we see the consumptive patient remove a hare-skin, or some other covering from his sternum, before examination of his chest ?

The knee consists of a mass of bone and cartilage, and is destitute of muscular covering, and there being thus a deficiency in the means of generating heat, it is consequently liable to suffer

from cold in cases of failure of the circulation. Sir B. Brodie, I believe, attributes the greater frequency of disease of the knee over that of hip-joint, to the latter being well protected with a fleshy covering.

Since we have such a useful office for the beard and whiskers, it may be asked why women are without them. I can only answer that they are not provided with the same means in other respects of resisting injurious agents as men are; nature has adapted them morally and physically for a domestic life; their long period of gestation, and the constantly recurring wants of infants, together with their protracted helplessness, pointing out that to man must be left to bear the inclemencies of the weather, and to sustain the fatigue of out-door labour.

It is not easy to assign the efficient cause for this juxtaposition of hair and tissues. The composition of bone, cartilage, tendon, and fascia, is kindred with that of hair. The animal ingredient of all is composed of protein, ammonia, and oxygen, in varying proportions, according to Scherer; and bone earth. I believe, as a mineral ingredient, also enters into the composition of all. It is possible, therefore, that the above tissues may supply materials for the growth of hair to integuments lying immediately over them, by means of imbibition, or in some other way with which we are not acquainted.

CONTRIBUTIONS
TO
ANATOMY AND PHYSIOLOGY.

BY ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

[Continued from p. 367.]

Hermaphroditism: a Memoir read to the Royal Society of Edinburgh in 1827 and 1828.

PART III.

EXAMINATION OF THE DUCTS OF MALPIGHI, SHEWING THEM TO BE THE VASA DEFERENTIA.

WHEN we examine the female organs of generation of the human species, we observe the parts to be such as I have

described them in the preceding section of this memoir. But in the internal organs of generation in certain animals, such as the cow and pig, and I presume in others in which the structure may not have been looked to, we find almost always present two elongated, and not unfrequently interrupted tubes or ducts running parallel with the horns and body of the uterus, and generally communicating with the vagina close to the orifice of the urethra.

The interior of these tubes seems to be lined by a mucous membrane; they never communicate either with the ovarian or fallopian tubes by the peritoneal extremity, and on this point the ancients, who knew well their presence, as has been abundantly shewn in the preceding part of this memoir, committed great errors, and made assertions in no respect true, nor borne out by the anatomy of the parts. Their anatomy is very simple: Bauhin has described them; he followed Galen, and was followed by Malpighi; they have been seen by, and are known to, all anatomists, and the attention of the physiologist was particularly directed towards them by Dr. Gœrtner, but unsuccessfully, inasmuch as no new facts were brought out by him, and thus the subject remained as mysterious as ever. It is sufficiently curious that modern observers should even have retrograded in their knowledge of the anatomy of these ducts, since in despite of the observations of all anatomists, two excellent zoologists, who may be supposed to speak the language of the school to which they belong, have denominated these tubes or ducts, utero-vaginal. The fact of their never communicating with the uterus has been admitted by all exact anatomists. They continue to be called the ducts of Malpighi, although he neither discovered nor described them well. Moreover, he fancied them to be female organs, though they be truly and strictly male.

Description of the ducts.—The minute verbal description of "the ducts," as they usually appear in the cow and pig, laid before the Society during the reading of the memoir, need not for obvious reasons be repeated here.

Description of the preparation.—This description, I regret to say, I am forced to give a good deal from recollection. On referring to my notes, I find

that no very minute account of the structures has been preserved; the preparation being before me when I described it to the Society.

Moreover, I unadvisedly dried the preparation after injecting "the ducts" with quicksilver, filling thus very fully the glandular structure of the testes to which these organs led, and thus I cannot return to it with any hopes of correcting any error I may commit by re-describing the preparation. I have thought these remarks due to the reader and to myself. (1843)

The uterus and internal organs of generation generally, together with as much of the external as could well be removed, belonging to a pig, which during life had distinctly shown an appetite for both sexes, were sent me by my friend, Mr. Alexander, of Preston Pans. The animal was when slaughtered about 1½ months old, and weighed 15 stone Dutch weight; the skin was remarkably thick and coarse, and although it had been well fed, was far from being fat: in temper it was ferocious, and according to the written account I received with the specimen, it did not discharge its urine in the usual way of either male or female, but between the hind legs; a clitoris, or, as it is called by the reporter, a penis, might be seen here, and the entrance of a vagina.

"It was possessed of a very strong desire as a male for propagation, and at certain seasons, by the appearance of the vagina, nature seemed to operate upon it as strongly as upon a female."

(Signed) T. ALEXANDER.

The above is all the information I received with the structures.

On examining the structures themselves, I find an imperfect penis; the vagina and uterus normal; the fallopian tubes defective, but not altogether wanting; "the ducts of Malpighi" in their usual place, and filled with a whitish fluid: on being injected with quicksilver, this penetrated easily, and on both sides, filling organs which proved to be two fully developed testes, with an epididymis, numerous seminal tubes, blood-vessels, &c. Connected with these testes intimately there lay above and towards the inner side two other organs, that is, one on each side, whose structure could not be well made out. They seemed to me, in fact, to be

ovaria: a hasty conclusion, I admit, since, so far as I can recollect, neither a distinct parenchyma, nor well-formed fimbriated extremity of the tubes leading towards them, could be made out. I regret exceedingly that a more minute examination was not made when the parts were fresh, and the drying of the preparation, with a view to its exhibition to the Royal Society, renders any return to it, with this view, impossible.

The inferences I draw from these observations and structures are, that this animal was to a remarkable degree hermaphrodite; that its œconomy and form were influenced deeply by the presence of male and female organs; that it could act as a male, and propagate as a female, may or may not be admitted, as not being essential to the question. Were female organs present together with the male parts? No one can doubt this; and though the absence of the ovaria, if they really were entirely absent, deprived the individual of those powerful regulating organs which constitute the female, affect the structure, her feelings, and, speaking of the woman, her moral existence, alter and change the proportion even of the skeleton; admitting that these organs were absent, still the uterus was present; and although no one in the present day will allow the accuracy of that aphorism of Hippocrates which says, "*propta solum uterum mulier est quod est*," it cannot, I think, be reasonably doubted that the presence of the female organs, including vulva, vagina, and uterus, with the appendages ligaments, implied a high approach to hermaphroditic structure.

The organs of generation, both in male and female, are frequently present only in sections; and they influence the structure of the whole frame in sections also. Thus we may have one side of the body of female form, the other side male; a portion of the pelvis male, and another female; the vagina may be complete or interrupted; and the uterus present or absent in both cases, or partially so; the presence, in short, of any organ or portion of the generative organs does not necessitate the presence of others; but we shall consider this exceedingly interesting subject in the concluding part of this memoir. This preparation, then, has disclosed to us the fact, singular and extraordinary in

itself, that in the females of certain animals the male vasa deferentia are almost always present*; that they have been mistaken for female organs for 2000 years; they offer us a key to the laws of hermaphroditism. They explain nearly all the phenomena of hermaphroditic structure, from the free-martin of Mr. Hunter to the perfect human hermaphrodite of Petit. When I have next the honour of addressing the Society I shall shew that the theories which teach us that hermaphrodites are imperfectly developed males, or imperfectly developed females; that the embryo is at first of no sex; that the male and female organs are identical, synonymous, and convertible into each other in the embryo state; and that deviations from the regular structure in man are proofs of his being *forced*, during the fetal growth, to pass through the various grades of animal organization, are doctrines partly devoid of foundation in truth, or are purely abstract and metaphysical; and if admitted to be abstract and metaphysical, do not even then correctly express the great transcendental law of *types of animal form* intended to fill all *material space* known to men, and types of animal organs, or of an apparatus of organs intended to perform a similar or strictly analogous function: all which forms or types being included in the great formative idea, do not *require* to be constantly reproduced in the embryonic forms of man, or of any other animal, necessarily: the type of the respiratory organs, for example, is in all embryos double, that is, aerial and aquatic, pulmonary and branchial; nor, in order to

prove this, is it necessary to suppose that the human embryo is *forced* to pass through lower grades of organization to a higher; neither can it be reasonably required of any anatomist to prove the existence of the rudimentary organs in all and every case; it is surely sufficient that such occasionally exist. In like manner I say of the generative apparatus, this type is double, is hermaphrodite, in fact. We see it so in plants and in many animals; we see it so, or nearly so, in the embryo of certain animals; and lastly, its traces, even in the adult human frame, are occasionally indisputable.

PART IV.

ON THE LAWS OF HERMAPHRODITISM, AND ON THE TYPE OF THE GENERATIVE ORGANS IN ANIMALS.

THE discovery of the persistence of the vasa deferentia, and occasionally of a portion of the vesiculæ seminales, in the adult females of certain ruminating and pachydermatous animals, recalled to my mind all that I had seen and read of organs whose exact nature and probable functions had never been accounted for on rational principles; and I returned to the subject with the hopes of solving certain physiological problems of avowedly great difficulty. It then seemed to me evident that organs exist in the males of various animals, which by their structure and nature are essentially female, and *vice versa*; and this fact, for assuredly it is one, naturally led to the inquiry, why they should exist at all? I need not, I think, remind this learned society that a problem of this kind may be solved in a variety of ways. First, it may be said that, as the male and female of any species of animals are obviously formed upon one plan, so we need not be surprised that the rudiments or remains of male organs are occasionally found in females, and *vice versa*; secondly, that they may be present from analogy, nature "delighting in analogies;" thirdly, when excessive or unnatural, their presence may be owing to a *lesus nature*; lastly, we may cut short all inquiry by an appeal to final causes.

With the view to determine these questions in a somewhat different manner, I shall endeavour, in the second part of my memoir, to bring

* I presume that it is not necessary to remind the reader that when Malpighi asks if these tubes may not be "vasa deferentia," he uses simply the expression, employed by all the anatomists of his day, to designate the vessels conveying the female seminal fluids from the ovarium, which he always called testis muliebris, and the vessels conveying the fluids from it the vas deferens.

Malpighi's notions about the nature of these ducts may be gathered from the following quotation:—"An nero (Jacobo Spon. par Celsus Malpighius, S. S. P. p. 34) uterina vasa superiora exposita huic fecunditati aliquid confestas debitari potest. Et primo probabile est, contentum succum feminei seminis vel saltem pros statum ichoris loco esse, et inde incipientium, et propriam energiam, et cum masculino semine ovo communicare posse. Quoniam tamen hæc vasa per longum uteri producuntur et extremis limbus ejusdem cornua irrigant glutinosa, pariter succo turgent, graviditatis præcipue tempore; ideo mihi dubitandum," &c.

in review the more striking deviations from what we term the regular structure, confining my inquiries chiefly to the structure of the generative organs, applying to them the various theories which have been proposed for their explanation.

From the very earliest of recorded times there have appeared, from time to time, beings of an equivocal nature as to sex, appertaining to the species of animals naturally disunited by the sexual distinctions of male and female. The ancients, when they found both kinds of organs regularly occurring in the same individual, in any of the lower animals, unhesitatingly pronounced the being hermaphrodite; but if this accidentally took place in an animal high in the scale, the appearance bore the character of a prodigy. If it happened in the human race, it indicated the approach of terrible events. Almost all the older writers detail unexampled cruelties which were inflicted on such unfortunate beings as came within the grasp of ignorance and superstition. It is true that the scientific, even of those terrible times, raised, as became them, their feeble cry against these outrages on humanity and common sense, but most frequently without success. The grounds on which they proceeded were, indeed, generally erroneous; and hence, perhaps, the reason why little attention was paid to their dicta: they either called the beings to which we now allude *lusus naturee*, which, of course, with every rational person, not medical, was a phrase so unintelligible and absurd, that they very naturally paid to it, and to the opinions of those medical men who employed it, no attention whatever; or they denied that there existed such beings as hermaphrodites in any of the higher animals, and to make good their assertion, every thing like logical reasoning was set aside. As a specimen of how far a wilful misrepresentation of obvious facts may mislead a person, and of the kind of reasoning employed by physiologists even to a period so late as 1750, I shall quote a passage from a respectable continental author.

"We may then still, resting our opinions on the case of Michael Anne Dronart, and on a number of others, believe that there will never be true hermaphrodites. Although nature

makes exceptions to her laws (*s'écarte de ses lois*), she still maintains a certain regularity in her works, and perhaps has even in view, in her caprice, to conceal from us, under a '*bizarrierie industrielle*,' which occupies us entirely; but we shall never see both sexes in the same person: the temperament of the one and of the other sex is too different to allow of their being found together in the same individual, and there is no example of there being found, in the same persons, the genital organs of both sexes, perfect as to number and conformation; and even when such a case shall occur, it would be an absurdity to suppose qu'il peut en même temps concevoir et engendrer," &c.

It were easy to shew, even from the treatise itself on hermaphrodites by Dr. Parsons, that the assertion that no such appearances as hermaphroditical existed, is without foundation in truth; but we need not, at the present moment, dwell on these points, which some may fancy to have been refuted long ago; and yet these opinions of Dr. Parsons are supported by the very learned Portal, in his *Anatomie Médicale*, and who assuredly is an anatomist of high reputation. There is a single remark I may make regarding the definition of hermaphroditism: if it be required to show the existence of what may be called efficient hermaphroditism, in man or in any of the mammalia, this may be found difficult; but if, to constitute this state, it be sufficient to prove the existence of male and female organs in the same individual, and these organs more or less perfect, then this proof is already before the public. Neither will it, I presume, be at all necessary to consider the doctrine of the congenital union of germs, a doctrine which any one at all acquainted with anatomy will readily perceive is in no shape connected with hermaphroditic structure.

When we examine the structure of the human generative organs, we perceive that there are male organs in the female body, and female organs in the male. So long as these do not exceed a certain standard, the appearances are termed natural, and the question as to the reason for their presence does not force itself on the mind. In some animals, such as the ruminants and

the pig, additional organs are observed to be almost constantly present; and this, though a remarkable fact in itself, and worthy of the most extended inquiry and the deepest consideration, comes at last to be neglected by most observers.

When additional parts appear, and the nature of the organs becomes equivocal — when male and female organs are found in the same individual, imperfect perhaps in their function, but effectual in modifying and altering the whole economy of the being — the appearances are then deemed worthy of notice; they are termed hermaphroditical. So long as these appearances are on a small scale, they do not affect the general economy of the being, nor do they attract notice; but whenever, by a law of nature which I shall endeavour to explain during the present memoir, these supernumerary or additional parts acquire an augmentation of bulk, they affect the whole economy. Mr. Hunter, who investigated everything with so rare a talent and success, has left us an admirable memoir on the free-martin, that is, the hermaphroditic ox. He was not aware that a slight approach to hermaphroditism almost always exists in black cattle or the pig; the dissections proposed by him are merely more advanced stages of the hermaphroditism of which I speak. The specimen which he received from Mr. Wright is less perfect than that I submitted to the Society at last meeting; and therefore I have represented it second in the diagram, immediately following the drawing of the parts in what may be termed a natural state. The third figure on the board presents us with a remarkable instance of Mr. Hunter's sagacity and acute anatomical observation: he has named the interrupted portion of the tubes of Malpighi (L. L.) *portion of the vasa deferentia*, although there were no testes present in the case he examined: the vesiculæ seminales, however, are present, together with the uterus, and he was aware that the animal, although it more resembled, in external appearance, the cow than the bull, was yet equivocal. In the fourth figure we have the remains of all the internal organs of generation, being almost a complete mixture of the male and female. The external appearances and

general character corresponded, it being neither that of the bull nor cow, but of a mixed character. A still more complete approach to hermaphroditism has been recorded by Mr. Homes, in an early number of the Medical and Physical Journal. In this case all the male organs were complete, and, in addition, the vagina, uterus, and fallopian tubes, with rudiments of the ovaria.

It may be supposed by some, that hermaphroditical appearances, such as those I have spoken of, are limited to animals which are usually considered as lower in the scale of animal creation; but this of course is a great error. Mr. Lee has related a case of a human being, in whom a testis was found on one side of the body, and an ovary on the other. Maria Nowra appears to me to have been completely hermaphroditical.

[To be continued.]

SOME REMARKS
ON
THE CLIMATE OF MADEIRA AND
THE AZORES.

BY JAMES B. THOMPSON, M.D.
(For the Medical Gazette.)

THE invalids, after their arrival at Madeira (which generally varies from eight to ten days from leaving England by sailing vessels, but sooner if by steam boats), are never so well as while the wind the "Leste" continues. This wind appears to affect the older residents more than casual visitors. It is attended with a peculiarly clear and cloudless sky, and the atmosphere is most agreeable, communicating a buoyancy and vivacity of spirits experienced but occasionally in tropical climates; the weather during its continuance being most delightful; the sky of a deep blue so stainless that one might fancy it had never been sullied by a cloud; with a transparency in the atmosphere which, like the effect of moisture, seems to bring out fresh hues from every object. The nights, too, are delicious, soft, and balmy; and in moonlight nights you may suppose yourself walking in summer and mid-day brightness: the orange trees in flower, and the air surcharged with the most agreeable fragrant perfumes. With the departure of the "Leste" rain almost invariably follows; and now

what you may call the sickly or least agreeable part of a Madeira climate is experienced.

The superiority of the climate of Madeira consists in the uniformity of its temperature. It differs, perhaps—in summer and in winter—less than in any known place north of the tropic. The thermometer commonly ranges from 60° to 75° ; and in the greatest extremes seldom sinks or rises more than five degrees below or above that medium. (For further particulars on this subject see the Report on the Climate of British Colonies, in the LONDON MEDICAL GAZETTE, Aug. 25, 1843.)

The climate of the group of islands called the Azores is very agreeable, and probably more suited to some constitutions than that of Madeira. The geographical position and general geological characters of the Island of St. Michael's renders it peculiarly eligible for patients labouring under tubercular complaints in an incipient form; for at any remoter stage, I look upon it as worse than cruel to recommend patients to leave their friends, when there can be no prospect of restoring permanent health; and you sever them from those fond ties and associations, at a period when, of all others, they require the soothing and condoling influence of friends and relatives.

St. Michael's appears to have been originally a plain, covered with very beautiful trees, rich verdure, and aromatic plants; at the present time, however, it consists of a number of mountains, hills, and declivities, none of which are primitive, but evidently the production of volcanic eruptions. The mountains and hills clearly indicate this, by their conical figure, and the reservoirs on their summits (craters), from which, it would appear, the volcanic discharges emanated. These islands bear evident marks of being the production of fire, as may be quite obvious to any visitor, from the unequivocal signs of the effects of that destructive agent, in an accumulation of lava, scoria, and volcanic sand. The same applies to the islands in the South Pacific Ocean—New Zealand, the Chatham Islands, &c. &c. The oranges grown at St. Michael's, as all the world knows, are highly prized for their superiority.

In any remarks on climate, it is desirable to give the most accurate data

as to the size and position of the places referred to. This group lies between 37° and 40° of north latitude, and 25° and 32° of west longitude. The islands are nine in number, and enjoy a very clear sky and salubrious air. They are extremely fertile in corn, wine, and a variety of fruits. The inhabitants breed a large quantity of cattle. The wine called *Fayal* is chiefly raised on the Island of Pico, which lies opposite to Fayal, and is the largest of all the Azores. These islands have greatly suffered by earthquakes. They were first discovered by Martin Behaim, and got their name from the number of *hawks* observed on them.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

The Physiology of Inflammation, and the Healing Process. By BENJAMIN TRAVERS, F.R.S. &c. London: 1844. 8vo. pp. 226.

MR. TRAVERS has endeavoured in this treatise to steer a middle course between orthodox Hunterians, and the mere slaves of the microscope; and to “extend our acquaintance with the phenomena of inflammation, as far as the present state of science permits, by the joint aid of physiological and pathological observation, each deriving force from the other.”—Preface, p. vi.

He has divided his work into twelve chapters, besides an introduction; their subjects are as follows:—Preliminaries: direct effects of stimuli and of wound; local symptoms of inflammation; constitutional symptoms, or effects of inflammation on the system; the processes of inflammation. Effusion; adhesion: periodical phenomena of wounds, illustrating the progressive stages of the healing process. Dried specimens: granulations and pus; suppurative inflammation; periodical phenomena of wounds, illustrating the progressive stages of the healing process. Recent appearances; ulcerative inflammation; cicatrization; gangrenous inflammation, and gangrene.

The following extracts will give a favourable notion of our author's topics, as well as of the manner in which he handles them:—

“1. The occasional causes of inflam-

mation are many and various, chemical, mechanical, and vital; the immediate cause is one and uniform. Cold and heat, wounds, foreign bodies, stricture, and poisons, are chief among the former; the latter is an interruption to the proper circulation and uses of the blood in the part affected. Spontaneous inflammation, a term in common use, is a solecism in language. Inflammation is always a forced state, however temporary and susceptible of resolution.

"2. The interruption above mentioned varies in degree as inflammation varies, and its signs or symptoms are demonstrated accordingly.

"3. The actions or processes of inflammation are several and well marked, and bear reciprocal relations to each other, influenced by the character of the inflammation; under which term I include its origin, intensity, extent, duration.

"4. The tendency of inflammation to preserve or destroy is not to be confounded with, much less employed to designate, its pathological character and denomination; because all its actions are capable of serving, and actually do serve, both salutary and destructive purposes, determined by the existing circumstances of the part or the system, as time, place, order, need, degree. Thus adhesion is often destructive, and gangrene conservative; and the same may be said of suppuration and ulceration." (P. 24.)

And a little farther on:

"7. Inflammation is not the less inflammation because the development of one, or even all its signs, is so feebly and obscurely manifested as to render its presence questionable to inexperienced observers, or because of its occasional tendency to yield in a remarkable manner to the operation of stimulants, even in its commencement. An eminent writer* has assumed that inflammation is not favourable, but adverse to healing; that it interrupts or retards the process of restoration when its presence is indicated: that therefore all our efforts should be directed to prevent inflammation coming upon wounds and injuries. If the epithet 'undue' or 'unnecessary' be prefixed, there is no difference between us. From the slightness of many injuries, and the

concurrence of good habit of body, the exaltation of sensibility and of heat, the increase of fulness and of colour, are imperceptible, and it is to continue this happy state of imperception, and to prevent their becoming palpable, that rest, position, and cooling applications and medicines, are enjoined; in other words, it is to preserve the subdued state of inflammation, which favours healing, and not to supersede it, which would more effectually retard or preclude healing, than the aggravation caused by an improper treatment." (P. 23.)

"Pain, like all modifications of perceptive sensation, has its source in the brain, although it is referred to as if it were seated in or emanating from the inflamed part. This is only partially demonstrated by the experiment of intercepting the nervous communication; because, while the circulation continues, the proper nerves of the blood-vessels escape division. But in a complete arrest of sensation and voluntary motion, as from a certain amount of injury to the brain or spinal chord, the circulation continues, and the sensation of parts so situated is equally deficient when undergoing inflammation, as in others not so affected.

"The following curious observation offers no exception:—A gentleman, whose spine was broken low down by a fall in hunting, and who was utterly deprived of sensation and motion of the lower limbs, had sloughing of the right hip, exposing the gluteal and trochanter, the surrounding integument hollow and bagging, *i. e.* no adhesion, and an unhealthy pus in abundance. On this hip he had been constrained to lie, and lay without pain; but on the other (left) hip, though repeatedly attempting it, he could not lie without severe pain; though inflamed on the point, it had not gangrened. Being equally insensible on both hips, he was at a loss to comprehend how this difference could be explained. The displacement of the fracture was on the left side, and the effect of pressure on that hip was to irritate the left lumbar plexus at the joint site of its division and emanation from the chord. Thus pain is referred to parts utterly devoid of sensation." (Pp. 41-2.)

The following observations will be familiar to the judicious practitioner, but they can hardly be repeated too often.

* The late Dr. Macartney, of Trinity College, Dublin.

"There are two false doctrines concerning blood-letting for inflammation, which cannot be too strongly condemned; the first, anticipatory blood-letting, by which I mean, the large and repeated detraction of blood before inflammation, being considered inevitable, has actually manifested itself—on the hypothesis of starving the action, and thus rendering it tractable—which is a direct attack on the vitality, and fatally perverts the action, if it do not destroy the resisting powers of the system. The second, continuing the employment of the lancet so long as the last drawn blood exhibits the signs of inflammation, which if drained to the last drop it would do; or, in other words, not reflecting that there is a line beyond which the practice becomes destructive instead of remedial; and that there are many inflammations which do not admit of arrest by depletion, and upon which other modes of treatment are efficient for this end, even though not an ounce of blood be drawn. Many lives have been sacrificed to the prevalence of these irrational and absurd notions, and many preserved in their extremity by being fortunately placed beyond the reach of the surgeon; especially, I am induced to believe, in military practice." (Pp. 58-9.)

The College of Surgeons possesses a series of preparations made by the late Dr. Todd, of Brighton, illustrating the healing process after wounds in the web of the frog's foot, in their daily progress to complete recovery.

As the preparations are unaccompanied by any description, Mr. Travers thought it necessary to repeat these experiments, in which he was assisted by Mr. John Quckett, one of the students of the College of Surgeons.

We regret that Mr. Travers should lend the sanction of his high name to experiments, by which much is inflicted on animals, and little, if any thing, is gained to man; yet compared with the proceedings of ordinary vivisection, the mere laceration or burning of a frog's foot may appear commendable.

Here are two examples of the appearances; the figures represent the number of days after the operation.

"Lacerated and contused wound by a sharp blow with a blunt body."

2. Clots of extravasation or ecchymosis on angles and borders of wound; no surrounding circulation.

4. Idem. Appearance of stagnant blood distending a large vessel passing nearly round the lacerated edge.

7. Wound has a more defined smoothed edge; slow circulation commencing in its vicinity.

11. Much exudation and congestion in the neighbourhood, and highly injected capillaries; but no trace of circulation.

Actual cautery, or heated iron.

2. Discoloration, opacity, and stagnation, of surrounding blood-vessels, which are gorged.

4. Blood still stagnant; margin of burn somewhat less opaque.

7. No circulation, but distinct demarcation of injury by a lightly-coloured margin.

11. Found dead." (P. 131.)

Mr. Travers' work is a summary, and more than a summary, of the present doctrine of inflammation, and will find a place in every complete medical library.

Essay on the Physiognomy of Serpents.

By H. SCHLEGEL, Doctor in Philosophy, &c. Translated by THOMAS STEWART TRAILL, M.D. F.R.S.E. &c. Edinburgh: 1843.

A curious and interesting work. It contains a complete history of serpents, their anatomy, physiology, geographical distribution, &c. &c., with portraits in which it is interesting to trace the varieties of form and expression which the head displays; indicative (when once the key has been given) of the disposition and properties of the animal.

"In examining a series of living animals, the attentive observer will remark, that, in their features, in their looks, and even in their forms, he may trace the expression of certain dispositions, habits, and passions, which are still more directly than in man the result of organization. On reiterating his observations, he will not fail to recognise by their features the different species of animals; he will seize the relations which link the species to each other; he will bring them together, and in this synthetic process he will arrive at a natural method. A series of beings thus grouped will produce an impression of the whole similar to what he would receive from a single individual,—an impression which it is necessary to depict as a whole, to

obtain a knowledge of its principal features.

"This manner of examining nature is, indeed, diametrically opposed to that which sets out to distinguish individuals from isolated characters; but, as it offers the only means of tracing a faithful picture, as it sets free the intellect chained in the narrow bounds of artificial methods, we should early fix the attention of the young naturalist on the universality of these views, and accustom him to seize, at a single glance, all the features which, by their union, form the peculiar character of each individual."

To the anatomist this little volume cannot fail to be interesting; but it is scarcely suited to the general reader, or medical practitioner who seeks chiefly for practical information.

A Practical Chart of Diseases of the Skin. By GEORGE ALFRED WALKER, Surgeon.

This is a large, neatly executed chart, fitted, and, we presume, intended to be hung up in the surgery or study of the practitioner. It contains a graphic description of the principal diseases which affect the skin, whether usually coming under the denomination of cutaneous diseases, or not (such as measles, scarlatina, &c.) It gives the same kind of information, in a condensed form, which we find in Willan, Bateman, and similar works. The principal recommendation which it possesses is, that if framed and hung up it will be more easily referred to. Nothing of the kind can be more neatly executed.

The Warm Water Remedy.—A Treatise on the Warm, Vapour, and Medicated Baths, with Directions for their Use. By HENRY WEEKES, M.R.C.S.L. &c. London: 1844.

This is a mere brochure, containing very little either of novelty or interest. The author strongly urges the more general use of the bath in this country, and we agree with him that its more extensive adoption would be very desirable. The portion of the pamphlet which contains most of interest is that which relates to the "medicated bath," and from this we give an extract containing the most important points.

"Medicated baths may be classed

according to their effects on the system, as stimulating, anodyne, absorbent, &c.; or they may be divided in a more practical manner into those which can or cannot be respired.

1stly, Those which *can* be respired:—

The Conium bath.

The Opiate bath.

The Nitric Ether bath.

The Chlorine and Iodine baths, much diluted.

2dly, Those which *cannot* be respired:

The strong Chlorine and Iodine baths.

The Sulphur bath.

The Mercurial baths.

The Nitro-Muriatic bath.

"This latter division including the non-respirable baths, does not, correctly speaking, come within the scope of this treatise; as these agents are not at all administered with the vapour of water. Still they are intimately connected with the foregoing ones, in being *external remedies*. They are principally used in diseases of the skin, and their success over other remedies in these obstinate affections has been very great.

"The exact strength of the bath to be employed will entirely depend on the nature of the disease, and on the age and constitution of the patient; for such is the idiosyncrasy of some persons, that the proportions of the medical ingredients can only be determined on by individual experience.

"The Conium and Opiate baths are indicated in various painful *nervous* affections, being eminently serviceable in lumbago, sciatica, and tie-doloureux. Their anodyne qualities also render the simple vapour bath better adapted for the relief of gout, and those painful swellings of the joints which often result from acute and chronic rheumatism. When about to be used, the ingredients should be infused for some hours previously to their ebullition.

"The Nitric Ether bath, being a combination of the vapour of Nitric Ether with that of water, speedily produces, from its stimulating effects, great capillary excitement and profuse perspiration. It will, therefore, be found serviceable where the latter is an important object; and should we be ever again subjected to the dreadful visitation of the cholera, this bath would certainly be deserving of trial in that epidemic.

"Chlorine gas, considerably diluted, has been respired in pulmonary consumption with the most beneficial results; and in the *early* stages of the complaint, some well-authenticated cures have been effected. By surrounding the whole body with an atmosphere of this gas diffused in the vapour of water, the respiration of the patient is easy and natural, which is not the case in the way in which this remedy is at present generally administered.

"The Iodine vapour bath furnishes us with a mode of treating serofulous affections in a simple and most satisfactory manner. Here the external and internal administration of Iodine can simultaneously be afforded the most delicate invalid. Cases of chronic serofulous inflammation of the eyes have been cured with this bath after the failure of all the usual remedies. In serofulous tumors and ulcerations, as well as in some skin diseases, a *strong* Iodine vapour bath (unfit for respiration) has been found successful.

"I have inserted the Nitro-Muriatic bath of Dr. Scott, which was some years since introduced by that gentleman as a remedy for various kinds of liver complaints, and was stated to have been very efficacious both in India and England. As the medical agent is chlorine gas, evolved in the bath by the union of the two acids, this inconvenient process can now be avoided by adopting the use of the vapour chlorine bath."

MEDICAL GAZETTE.

Friday, January 5, 1844.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

NEW CHARTER OF THE COLLEGE OF SURGEONS.

THE most remarkable feature of this charter is undoubtedly the institution of a privileged class, under the title of Fellows. On this we offered some comments in our last number. We noticed also some of the changes effected in the composition of the Council, or

governing body. We stated that this body was henceforth to consist of 24, instead of 21 members as at present; and we intimated our intention to explain, in an early number, the mode by which the charter directs that all future vacancies in the Council should be filled up. We proceed to redeem our promise.

The first circumstance that strikes us as particularly worthy of notice in this respect, is that clause of the charter (12) which directs that in all cases, Fellows going out of office shall, notwithstanding, be eligible for nomination and *immediate re-election*, provided they continue in all other respects eligible. We do not see any objection to this clause, which enables the Council to profit by the matured experience of its oldest members; but it should be remembered, that the principle, if not kept in check, as it doubtless will be, by the watchful care of the electors, would, *per se*, lead to the very evils which the present system has been accused of engendering. All Fellows (including, of course, those who are already on the Council), are to have the privilege of voting at elections of members of the Council. No proxies are admissible. The election is to be by ballot, and to take place on the first Thursday in July in every year. Fifteen Fellows must be present before the ceremony of balloting can begin. So far so well. All this is plain enough, and all highly proper; but now we come to a series of measures, prerequisites to the election of members of Council, which we shall not probably succeed in rendering equally intelligible, or equally satisfactory, to our readers.

The nineteenth clause of the charter directs that no Fellow can be put forward as a candidate for election into the Council, unless there shall be produced at or about the same time (it not being specified which), a written certi-

ficate, signed by as many Fellows as the Council shall from time to time think fit to require, stating that he, the said candidate, is a fit and proper person for holding such office; that he does not, and has not for the five preceding years, practised midwifery or pharmacy, and that he resides, and *bonâ fide* practises, within five miles of St. Martin's-le-Grand. This certificate being duly handed up, in such way, manner, and form, as to the said Council shall seem good, then the said certificated Fellow may proceed to the ballot.

Again, if any *eligible* Fellow, that is, any Fellow resident within the prescribed limits, and not practising midwifery or pharmacy, either then or for five years preceding—if such a one has been passed by for want of such nomination, he shall cease for ever afterwards to be eligible, except upon special terms of nomination, to be arranged by the Council at their pleasure. So, in like manner, if any eligible Fellow, duly nominated as aforesaid, shall have stood the ballot, and not been successful, he cannot henceforth be brought forward as a candidate, except under the special terms of nomination applicable to the unhappy Fellow who cannot find friends to certify his fitness in that particular year. And what is more, if either the unnominated, or the unsuccessful candidate, should meet with the same bad luck a second time, “he shall ever thereafter cease to be eligible for election upon the Council.”

For the purpose of insuring the due fulfilment of these provisions, it is ordered (clause 17), that the name of every Fellow eligible in accordance with the aforesaid restrictions, “shall be announced to the meeting in the order, and according to the priority, in which his name shall stand in the Fellows' Registration Book.” The obvious intent of these restrictions on the

freedom of election, is to limit the number of candidates within reasonable bounds; and we clearly see the propriety of some laws to restrain the putting forward uselessly and wantonly a variety of candidates.

The new plan is intended to supersede that simple but not very liberal contrivance, generally known by the name of a *house-list*. Such a system is very properly discountenanced by the new charter; but we cannot, as at present advised, bring ourselves to think that the machinery brought forward as a substitute is likely to be popular. We can hardly persuade ourselves that it is very practicable. No provision is made as yet for obtaining the previous consent of the candidates to their nomination, though, of course, in the plenitude of their power, the Council may make such consent imperative. As the clause stands, it almost compels the Fellows to select one of the senior members of the body, for otherwise they themselves, like the candidates at the Blind Asylum, become superannuated.

Nothing is more natural than that the Fellows should desire to see their Council reinforced by a proportionate number of young hands. This has long been a desideratum in the Council, and it is, beyond all doubt, what is best for the public and the profession. But how this desirable consummation is to be brought about, except by superannuating a large body of Fellows, we cannot, as the charter stands, perceive. Supposing that a body of Fellows should agree among themselves to put forward at the elections in 1844 and 1845, six young members, by way of counterpoise to the 21 seniors now on the list, the result would inevitably be, that nearly every other existing eligible Fellow would be superannuated on the 5th July, 1845; that is, in a year and a half after the issue of the charter.

Surely an arrangement which even

admits of such a result as this (extreme though the case may be), cannot be a good one. It limits the choice of the Fellows in an indirect way, and in a way calculated to give pain. It savours too much of the old method of electing the Council, and might certainly be improved, with great advantage to the working of the charter. The simplest way of meeting the acknowledged difficulty, would have been to require that the certificate of nomination should be signed by so large a number of Fellows as almost to render his success a moral certainty. To insure a due admixture of seniors and juniors in the Council, it would have been easy to direct that, in alternate years, candidates for the Council should be selected from the senior or junior moiety of the list. Either of these measures would have saved the necessity of that harsh measure, the superannuation of members for defect either of nomination or of success. We will not dwell longer on this topic. If a revised charter should ever be issued, we doubt not but that it will come in for its fair share of consideration.

3. The construction of the examining body next claims our attention. Various alterations have been effected here, both with reference to the mode of electing examiners, their admissibility, and the period of their continuance in office. The number of examiners remains the same as at present, viz. ten; but the charter provides that, after the demise or resignation of the present examiners (who hold their offices for life), all future examiners shall be elected by the Council of the College, either from among themselves, or the general body of the Fellows. It is further stipulated, that they shall hold office during the "pleasure of the Council, and so long only as the Council of the College shall think fit." This is undoubtedly a great improvement upon the old system, coupled as it is

with the abolition of that antique regulation, which provided that the two Serjeant-Surgeons to her Majesty, and the Surgeon-General of her Majesty's Forces (whether competent or incompetent to the situation), should have a preference of admission as examiners before all other persons.

Hitherto it has been the law that the President and Vice-Presidents of the Royal College of Surgeons should be chosen exclusively from out of the ten Examiners. The new charter directs that in future those offices may be filled by any of the 24 members of Council. This is another most obvious improvement. In fact, in this part of the charter we find everything to praise, and nothing even to animadvert upon.

A few other points connected with the new charter of the College of Surgeons seem to require some brief notice from us. It will have been seen that the Council were directed to create from 250 to 300 Fellows in the first three months. It is provided, however, in clause 4, that this is not the maximum number of the Fellows. No maximum, indeed, is prescribed. The Council are empowered, during the ensuing nine months, to create as many additional Fellows (without any fee) as they shall think fit. How far they will be disposed to carry this privilege remains to be seen; but probably they will think it right so to restrict the number, that the Fellowship shall be in effect what it was obviously intended to be—A TITLE OF HONOUR.

The Council have the sole power of conferring the Fellowship, and there are no means provided for appealing against their decision, and no check upon any of their measures, except the following, which, so far as it goes, is excellent, and deserving of every commendation. The penultimate clause of the charter declares, that no bye-law or ordinance

hereafter to be made by the Council shall be of any force, until her Majesty's approval thereof shall have been signified by the Secretary of State for the Home Department. This virtually gives the profession an appeal to the Home Secretary against the decision of the Council—that is, provided the nature of the proposed bye-law or ordinance shall, by any accident, have oozed out.

The charter continues to the College and Council all those powers, authorities, and discretions, and all that same jurisdiction, with respect to the election and choice of officers, the admission and expulsion of Fellows and Members, and the regulation of matters pertaining to the government and advantage of the College, as have heretofore been enjoyed, save and except in those respects for which the act specifically provides.

We have, lastly, to offer a few observations to our readers on the manner in which the Council have exercised that first privilege which the charter confers upon them, namely, the selection of the original three hundred Fellows. The list appeared in a late number of the journal, and doubtless attracted the notice of our readers. The grounds on which the Council proceeded in their choice appear to have been the following. They began by giving the fellowship to every surgeon, and every assistant-surgeon, of every recognised hospital in England, without exception. Then they took every lecturer on anatomy and surgery, and every demonstrator at each of the schools attached to those hospitals, whether metropolitan or provincial. They then applied to Sir James M'Grigor, and, on his recommendation, promoted certain distinguished navy-surgeons. Sir William Burnett furnished his quota of deserving navy-surgeons. The Chairman of the East

India Company sent in his list of "honourable men," and these were forthwith added to the catalogue of Fellows. The Council then exercised their own privilege, and chose a certain number of gentlemen, chiefly surgeons practising in London, who had distinguished themselves in various ways. Mr. Bacot, for instance, was selected, as an Examiner of the Metropolitan University, and the Inspector of Anatomy. In several instances, the surgeons of dispensaries have been nominated. Mr. Ceely, of Aylesbury, was selected, most deservedly, for his labours in pathology; Mr. Blagden, and Mr. Stone, for their acknowledged eminence as accoucheurs. The list contains not more than one or two names of gentlemen acting as general practitioners. We have every reason to believe, however, that this arose, not from any unwillingness on the part of the Council to acknowledge the professional, scientific, or general merits of many of that class, but because the charter restricted their choice to 300, and the several classes now enumerated absorbed the whole number.

The Council appear to us to have fulfilled this part of their arduous duty with excellent taste and goodfeeling. Though we cannot reasonably expect that all will be pleased, yet we think the profession generally will acknowledge the judgment and impartiality which have been evinced in the selection of the first batch of Fellows. It is particularly gratifying to us to observe the civil and military classes of the surgical profession united in the ranks of honourable association; and the Council, in the discharge of their new functions, have in no circumstance earned a nobler title to our praise than in according, even with perhaps too liberal a hand, the honours of the fellowship to the absent but not forgotten members of their body.

FELLOWSHIP OF THE COLLEGE OF SURGEONS.

To the Editor of the Medical Gazette.

SIR,

IN the leading article of your journal of this date, you have coupled my name with a supposed examination of a member of the College, of 50 years of age, for the Fellowship; and as gentlemen not living in London may presume you have selected, or taken it accidentally, from my supposed affection for the new charter, I shall be obliged by your permitting me to make known to them my sentiments on this particular point of the Fellowship, viz.:

"That no person should become a Fellow or Elector (which is the sole office or duty of a Fellow) until after he had been at least seven years a member of the College, when he should be at liberty to become a Fellow on paying the prescribed fee; or by undergoing a special examination without paying the fee, if found deserving of such honorary distinction."

At Oxford and Cambridge, a man takes his degree of B.A. after a sufficient and approved examination, and becomes M.A. after a further prescribed study without examination; and qualifies himself as an Elector by paying the sum of thirty guineas, a precedent which might have been followed, I am of opinion, to the satisfaction of a very great majority of the profession.

I am, sir,

Your obedient servant,

G. J. GUTHRIE.

4, Berkeley Street, Dec. 30, 1843.

ON THE CORPUS LUTEUM.

By T. WHARTON JONES, Esq.

[THE following is the best account of the corpus luteum which has fallen under our notice.]

SECT 75. Baer's opinion, that the corpus luteum consists in a growth inwards of the inner layer of the Graafian follicle, is supported by Bischoff, in opposition to opinions entertained in this country, viz.—that the yellow substance is contained between the two layers of the walls of the Graafian follicle according to Dr. Montgomery, or that it is outside both according to Dr. Lee. Barry's statements appear to favour Montgomery's view, though, in reality, he agrees essentially with Baer, and that apparently without knowing it. Barry considers his "*ovisac*" as the inner layer of the Graafian

follicle; now Baer, in speaking of the inner layer of the Graafian follicle undergoing the change to form a corpus luteum, could not have referred to Dr. Barry's "*ovisac*," inasmuch as he did not know of the existence of such a structure, but to the inner layer of the cellulo-vascular wall of the Graafian follicle—the *covering of the ovisac* of Barry. All this, indeed, Barry is aware of; but, in sect. 157 of his second series, unnecessarily regrets to find himself expressing an opinion at variance with that of Baer, and in his subjoined note coincides with Montgomery in his view of the corpus luteum, but inaccurately, according to his own principles, inasmuch as Montgomery speaks of the layers of the Graafian follicle in the same sense as Baer.

SECT. 76. The fact is, Dr. Barry's "*ovisac*," or as Bischoff calls it, *tunica propria** of the Graafian follicle, exists only at the commencement of development, and is not to be found afterwards. "From my observations on the formation of the Graafian follicles," says Bischoff, p. 45, "I have, indeed, admitted a *tunica propria*, which becomes overlaid externally by a layer of fibres, and with this represents the follicle. But I have never found that this *tunica propria* admits of being separated as a distinct layer of the follicle, but have found reason for admitting it only in the process of development." Barry says (2nd series, p. 317, sect. 154), that in a few hours after the ovum has been discharged from the Graafian follicle, the "*ovisac*" may be readily removed by pressure from the burst Graafian follicle; but in sect. 155 he says, that at the end of several days the primitive ovisac is no longer met with in the ovary; and in a note he remarks, that he does not know whether in the interim the ovisac has been absorbed *in situ* or first expelled, but in the hog he has found what seemed the remains of ovisacs in the infundibulum. In reference to these statements Bischoff observes, that he has never seen that any *tunica propria* becomes loose from the rest of the follicle after the expulsion of the ovum. The gelatinous-like mass found in the follicle in the first period, after the escape of the ovum, he asserts, is by no means the *tunica propria* of the follicle of the *ovisac*, as it has been seen Barry thinks, but the fluid of the follicle and membrana granulosa which had not all escaped, changed and become more con-

* The terms *ovisac* and *tunica propria* are employed in the descriptive and illustrated catalogue of the museum of the Royal College of Surgeons, vol. v. in a different sense from that in the text. *Ovisac* is used for the whole Graafian vesicle or follicle; *tunica propria* is applied to the cellular and vascular wall of the Graafian vesicle, or Barry's "*covering of the ovisac*;" whilst *ovarian vesicle* is used for what is referred to in the text under the names of *ovisac* of Barry, or *tunica propria* of Bischoff.

sistent, and which by great development of its cells has been converted into a viscid coherent mass." Barry's own figure 98, plate 5, is corroborative of this assertion of Bischoff.

Sect. 77. To return to Montgomery and Lee. The cases adduced by these gentlemen unequivocally show, that human true *corpora lutea*, at least, are not growths of the inner layer of the Graafian follicle—the inner layer in the sense of Baer, and not of Barry—for in such *corpora lutea* not long after conception the inner layer is found but little changed, and not at all the seat of the yellow growth.

Sect. 78. The yellow substance, it is to be observed, is a new formation, and not a *conversion* of the cellular tissue of any part of the wall of the Graafian follicle, as appears to be the opinion of Baer, Barry, Bischoff, and the author of the notices in the Catalogue of the Museum of the College of Surgeons. The designation of the corpus luteum by the latter, as the "thickened parenchymatoid proper tissue, or tunic of the *ovisac*," must be held to be erroneous. From the statements in the catalogue regarding the corpus lutea in the College of Surgeons' Museum, it cannot but be admitted that the preparations support the views of Montgomery and Lee, so far as these two gentlemen concur, rather than those actually given in the Catalogue.

Sect. 79. As above stated, Montgomery is of opinion that the yellow substance is deposited between the two layers into which the cellulo-vascular wall of the Graafian follicle may be separated by dissection, whilst Lee maintains that the yellow substance is wholly outside both, and that any appearance of membrane between the yellow substance and the stroma of the ovary, which may in some cases present itself, is due simply to condensation of the neighbouring part of that stroma. From the examination he made of the very recent corpus luteum described by Dr. Lee, in the *Medico-Chirurgical Transactions*, a few years ago, the author of this report was led to concur entirely in this view; and it may be observed that the statements in the description of the corpora lutea, in the Catalogue of the College of Surgeons, are unequivocally to the same effect.

CASE OF A NEEDLE ENTERING THE RIGHT BREAST,

AND FINALLY LODGING IN THE HEART,
CAUSING DEATH,

By B. F. LEAMING, M.D.
Physician to the Philadelphia Dispensary.

ON the 4th of August, 1842, a sempstress, in good health, eighteen years of age, came

to my office, requesting me to remove a needle which she supposed had penetrated the right breast. Two days before, while in the act of bending suddenly forwards, she had struck a table, and driven a needle, which was sticking in her dress, forcibly into the breast. She was not quite certain that the needle was still there; sometimes she thought she could feel it, at other times she was sure it was not there. On examination I found a puncture about an inch from the nipple, a little below the margin of the areola, and on the side towards the sternum. Her breast was rather large; it could be pressed firmly in any direction without causing pain; she had no cough, and could take full inspirations without inconvenience.

On the 8th of September she had pleurisy of the right side; she had not been exposed to cold, but the pain and cough, and difficulty of breathing, had come on suddenly after she had stooped to pick something from the floor. The inflammation yielded to the usual antiphlogistic remedies, and in three weeks she regained her usual health.

On the 13th of February, 1843, she had a slight attack of pneumonia of the lower anterior part of the right lung; she had also bronchitis on both sides. She recovered in a week from the acute symptoms, though afterwards she was always affected with a troublesome cough.

On the 10th of March she had spasms of the diaphragm; they continued for three or four days, intermitting occasionally for a few hours. The inconvenience was not sufficient to confine her to the chamber. Until this time the pulse had been regular, and always corresponded to the degree of fever present.

On the 26th of March she had obstinate vomiting, not accompanied by tenderness at the epigastrium, nor by thirst for cold drinks, nor by constipation, nor by any cerebral symptoms whatever. The vomiting continued four days; it was always increased by drinks, though the efforts frequently persisted while the stomach was quite empty. During the intervals her pulse was 80, feeble and regular.

On the 5th of April she had pain in the heart. During my attendance to the previous illness of the patient, my prescriptions had been so much neglected that I declined visiting her any more; therefore I did not examine her symptoms particularly when called on at this time, (5th of April,) but requested the friends of the patient to seek advice elsewhere.

On the 8th of April she was visited by Dr. Franklin Bache, who detected the existence of pericarditis, accompanied by a very irregular and feeble pulse. From inattention on the part of the patient to Dr. Bache's prescriptions, his visits were continued only four days. She was then attended by Drs. Watson and Arrott, who found her in a very

prostrate condition, with irregular pulse, and sometimes so feeble that it could scarcely be felt; she had also the usual symptoms of pneumonia.

On the 15th of April she had œdema of the feet; and two days afterwards her face was somewhat swollen.

She died on the 27th of April, nearly nine months after the needle had entered her body.

On examination after death, the right lung was found adherent throughout to the costal pleura; both lungs were congested, and the bronchia inflamed; at the posterior inferior part of each lung there was some hepatization. The pericardium contained more than a quart of fluid blood; its surface was covered with deeply reddened lymph; some of the recesses formed by small folds of the pericardium, or by adhesions near the upper part of the auricles, were filled with grumous blood; there were adhesions at the under surface of the heart, particularly under the right ventricle, and in a line parallel with, and half an inch from the septum. The heart was small and flaccid, containing only small coagula. On opening the left ventricle the point of a needle was seen protruding a quarter of an inch towards the middle of the cavity. The needle had passed at the under surface of the heart about three-quarters of an inch from its apex, and half an inch from the septum, through the wall of the right ventricle, through a columna carnea, through the septum and into the left ventricle. It was fifteen lines in length; its head, somewhat inerusted, was imbedded in the wall of the right ventricle, just under the surface of the pericardium. The orifice made by the needle seemed to have been completely closed by coagulable lymph; but it would be very easy for a small channel to escape detection in such a mass. The internal membranes of the heart were smooth and shining, without any marks of inflammation; all the large vessels were in excellent condition.

Although the patient could never point to the situation of the needle, and was always unconscious of its presence in any particular part, yet, during my attendance, I never doubted that it was the cause of all her ailments. I presume it first lodged obliquely in the intercostal muscles, or was made to do so by her own attempts to discover its situation; it then passed through the pleura, and probably a portion of the lung, reaching the floor of the diaphragm; it then seems to have moved near the œsophagus, irritating some filaments of the par vagum; and finally, it reached the heart.

The blood in the pericardium may have derived either from the cavities of the heart, or from the inflamed adhesions, or from both. In the first case, we may suppose that every contraction of the heart separated the muscular fibres sufficiently to allow the

blood to pass along the sides of the needle; and the separation of the fibres of the walls of the right ventricle would be greatly favoured by the *working* of the needle, caused by its extremities being subjected to differently acting forces. It is true no channel through the adhesions of the pericardium could be detected; but in the relaxed condition of the heart a small channel through coagulable lymph would necessarily escape detection. From whatever source it derived, the blood was of good appearance, resembling that drawn from the arm of a moderately anemic person; it therefore could not have been much diluted by serum from the inflamed pericardium.—*Philadelphia Medical Examiner.*

PHARMACEUTICAL SOCIETY.

REGULATIONS ADOPTED AND CONFIRMED BY THE COUNCIL, FOR THE EXAMINATION AND REGISTRATION OF MEMBERS, ASSOCIATES, AND APPRENTICES.

CANDIDATES for the major or minor examination must send in their testimonials to the secretary, on or before the 1st day of the month, which testimonials must consist of—

For the minor examination, either an indenture of apprenticeship, or a certificate from a chemist and druggist, with whom the candidate has been regularly educated.

For the major examination, a similar testimonial, if the candidate be not already an associate of the Society; and he must show to the satisfaction of the board that he is in business on his own account, or intends to commence, or that he has been an assistant for the term of five years since the expiration of his pupilage.

The *minor examination* for the certificate of qualification to act as an assistant to a chemist and druggist, and to become an associate of the Society, is conducted in the London Pharmacopœia; embracing an elementary acquaintance with chemistry, materia medica (including a knowledge of the external character of indigenous medicinal plants), practical pharmacy, physicians' prescriptions, and the antidotes for common poisons.

The *major examination* for the diploma, as a member of the Society, is on the same subjects, but on a more extended scale.

Apprentices coming to reside within ten miles of London, must present themselves for the classical examination at the Society's house; beyond that distance, they are at liberty to undergo the examination by any qualified person, whose certificate, if satisfactory, will be received by the board.

Notice must be given to the secretary, on or before the 1st of the month, by apprentices coming up to the board in London; and forms of the certificate for the county

may be had on application to the secretary, which, when filled up, must be returned: when, if approved by the board, the pupil will be registered (and, on payment of the annual subscription of one guinea, will be entitled to enjoy the privileges of an associate).

The fee for registering the apprentices or pupils of members, is five shillings; if the master be not a member, the fee is ten shillings and sixpence. Every apprentice or pupil not registered within twelve months after the date of his indentures, must pay a fee of one guinea on presenting himself for examination as an associate (and those who neglect to register cannot be admitted to the privileges of an associate, without the special permission of the council).

The board of examiners meet on the third Tuesday in each month throughout the year, except in May and September, at eleven o'clock in the morning.—*Pharm. Journal.*

EFFECTS OF MEDICINES ON HORSES.

By MR. PERCIVAL.

Lead.—As an external medicament, no substance has been held in greater estimation, or been more generally used, than lead; and though surgeons of the present day ascribe less efficacy to it than did Goulard and his followers, yet it is still a frequent and favourite application to inflamed or swollen parts, and one that is believed to be productive of a great deal of benefit. Many veterinary surgeons are likewise in the habit of employing "Goulard lotion," as it is commonly called—the *liquor plumbi diacetatis dilutus* of the present London Pharmacopœia—but with what amount of efficacy seems rather doubtful. Professor Coleman declared it to be, for horses, in any strength, no better than so much cold water. And I must confess, though I use it, I have my misgivings, myself, about its local operation. It has one decided advantage—it has the appearance of being, and is by the public considered to be, medicinal.

What, perhaps, has tended to confirm its topical efficacy in human medicine has been its known power of producing even deleterious effects when administered in very small quantities as internal medicine: nay, the very effluvia of the mineral arising from surfaces recently painted is sufficient to excite in some persons very unpleasant effects or sensations; and we all know how generally unhealthy is the aspect of men employed in painters' work. This has deterred surgeons from prescribing lead to the degree or extent they otherwise might have done; and though they do so on occasions, in some diseases, with manifest advantage, every now and then it has happened that very unexpected

and alarming symptoms have followed its exhibition. In respect to horses, I have given the *acetas plumbi*—the sugar of lead, as we call it—both in glanders and in periodical ophthalmia: in neither disease, however, with any visible benefit. Its exhibition was as follows:—

To the first, a glandered horse, it was administered for several days in half-ounce doses morning and evening, without producing any effect, either on the disease or state of health of the animal.

To the second horse, having periodic ophthalmia, it was given in ounce doses twice a day for five days, without any noticeable result.

To the third horse, glandered, it was given on the first day, in the dose of an ounce morning and evening; on the second this dose was doubled; and on the third and fourth days, the two-ounce doses were continued morning and evening. On the fifth day the horse refused his food, and had an intermittent pulse; therefore the medicine was omitted. On the sixth day, however, the same doses were repeated; which on the seventh day produced such alarming return of the symptoms of nausea, dejection, and derangement of the pulse, that the medicine was from this time discontinued altogether.

In neither case did any symptoms of colic or palsy present themselves.

Zinc.—Another of the metals which, in veterinary medicine, has been more used as an external than an internal remedy: indeed, zinc has hardly yet found a place in our pharmacopœia as a medicine. I have notes by me giving some account of the exhibition of the *sulphate of zinc*: I have, myself, since administered in considerable doses the *oxide*.

Sept. 2d, 1804.—Two horses, in good condition, though having chronic discharges from the nostrils, commenced with taking doses of half an ounce of the sulphate three times a day, which they continued until the 14th, without manifesting any change either in appetite, pulse, or general appearance. The dose was now augmented to an ounce thrice a day, and at the expiration of four days from this, both horses manifested nausea, and appeared salivated, and refused their food. The medicine was discontinued for three days, and then resumed; it having been remarked in the interval that large quantities of urine had been voided. Two days afterwards, the disease in the nose having shown a tendency to spread, one horse was destroyed. His stomach displayed inflammation upon its vascular lining; but there was no other disease. To the other, the doses were still farther augmented, but without any novel result.

April 1st, 1813, a brown gelding came under my care for treatment for glanders. He was but three years old, and looked well in health and fine in his coat, although he

had two distinct ulcerations inside his off nostril; his submaxillary glands enlarged on the same side; with corded absorbents and two or three ulcerations upon the off shoulder. He feeds well and his bowels act regularly.

Let him take, morning and evening, half an ounce of the oxide of zinc, in ball, and have his swollen glands blistered, and his ulcers dressed with solut. cupri usulphat.

3d.—Increase the dose to one ounce twice a day.

5th.—Let him take his ball thrice a day: there being as yet no visible alteration, excepting that the ulcers in the nose are spreading. Apply to them red precipitate powder.

9th.—The medicine is not producing any effect. A fresh ulcer is visible in the nose. Let him take two ounces morning and evening.

10th.—Some knotty tumefactions are to be felt upon his quarters, and his hind legs have taken to swell.

11th.—The ulceration inside the off nostril is rapidly spreading, though its appearance has been improved by the red precipitate. Two small ulcers, however, are now discoverable upon the *near* side of the septum. Continue balls.

13th.—The hind legs are so much swollen that exercise is deemed requisite. The appetite, however, continues good, and there is no perceptible loss of flesh. Augment the ball to three ounces of zinc twice a day.

14th.—The disease keeps extending, but tardily. On this account the medicine was discontinued altogether, and the horse—after an interval—made the subject of a fresh experiment, the zinc having taken no effect whatever upon him.—*The Veterinarian.*

RECENT ELECTION AT ST. GEORGE'S HOSPITAL.

THE Editor of the MEDICAL GAZETTE is particularly requested to insert the enclosed note in the next number of the GAZETTE.

ELECTION AT ST. GEORGE'S HOSPITAL.

To the Editors of the *Provincial Medical Journal.*

GENTLEMEN,—Your Journal of the 23d, which has this day reached me, contains an account of the late election at St. George's Hospital, which states that I "was supported by all Sir Benjamin Brodie's influence."

I beg you will admit in your next number my denial of that assertion.

I was not supported directly or indirectly by Sir Benjamin Brodie, who neither voted nor took any part whatever in the election.

I am, Gentlemen,

Your obedient servant,

CHARLES HAWKINS.

The Court Yard, Albany,
Dec. 28, 1843.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

LIST OF GENTLEMEN ADMITTED MEMBERS.

Friday, December 29, 1843.

T. W. Houchen.—T. Coulson.—B. Baker.—A. Gosden.—B. Kemp.—J. B. Bridick.—J. H. Brown.—E. Wadams.—H. L. Hogg.—T. T. Chadwick.—H. J. Stokes.—W. Crofton.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, Dec. 21, 1843.

A. Parr, Liverpool.—S. Pratt, E. I. C. Service.—J. H. Llewelyn.—S. N. Elliott.—J. E. Hebblethwaite, Oporto.

Thursday, Dec. 28, 1843.

G. Keane, Ongar, Essex.—K. Burton, Wainflete Lincoln.—W. E. G. Wilson, Leeds.

ON PNEUMO-THORAX:

AN ESSAY,

*Read (in part) at the Physical Society of
Guy's Hospital,*

By H. M. HUGHES, M.D.

One of the Assistant Physicians to the Hospital.

[Continued from p. 440.]

The diagnosis of pneumo-thorax, with the aid of auscultation, percussion, and succussion, has usually been represented to be an affair of great simplicity, and when the entire progress of any case has been witnessed by any one observer, when the accession and the whole of the ordinary phenomena of the affection are well defined, when, in fact, pneumo-thorax exists as it is usually described in books, a very simple affair it is. But every really practical and observant physician is aware that at the sick man's side doubts and difficulties will occasionally arise, even in those diseases which upon paper are represented in characters apparently so clear as not to be mistaken. The diseases or conditions with which pneumo-thorax may conjecturally be confounded, are—1st, emphysema of the lung; 2dly, the tympanic resonance said to occur during the progress of pneumonia; 3dly, a flatulent stomach overlaid by a consolidated lung; and 4thly, phthisical cavities. Of the two first I shall say nothing. The former of the two I have, indeed, mentioned only because it has been customary to do so, as I believe that with moderate attention to the history, symptoms, and physical signs, it is scarcely possible that a mistake can arise. Of the latter of the two I forbear to speak, because I can say nothing derived from my own experience, unless indeed, as I already expressed my conviction, it may be referred to the third condition mentioned; viz. a stomach distended with gas, and overlaid by a solid and contracted lung. In this combi-

nation the absence of respiration and the tympanic resonance on percussion are often complete, and succussion occasionally exists. The side is contracted indeed, but sometimes, though rarely, it is likewise so in pneumo-thorax. The ribs are but slightly elevated, or almost motionless, and I believe that in a few rare examples the only circumstances upon which we can rely for the diagnosis of the two affections are the fistulous, metallic, or amphoric breathing, and the metallic ringing of the voice, and cough, which are constantly present in the one affection; the want of completeness, uniformity, and consistency in symptoms and signs of the other, and the history of the respective cases.

But of all diseases a large phthisical cavity is by far the most liable to be confounded with, and the most difficult to be diagnosed from, pneumo-thorax. I lately saw a case examined in the hospital, in which one immense cavern occupied the whole of the left lung, and in which, even after death, it was for some time difficult to decide whether the cavity was in the pleura or the lung itself. In such a case, excepting the history, I know of no circumstance whatever upon which a diagnosis could be formed, with even tolerable certainty. A few years since there was an elderly woman in the hospital, in whom all the facts of the history, the symptoms, and physical signs, led to the supposition of the existence of pneumo-thorax, with the single exception of the cavern being situated at the upper third of the lung. Upon inspection after death, a very large and old vomica was found, with firm and hard parietes, and nearly all the remainder of the lung dry, tough, and airless. In another case examined last year, a circumscribed pneumo-thorax, of the size and shape of a foetal head, existed in the left mammary region, which presented all the physical characters of a large vomica. I lately attended a young medical man, during whose last illness I had once the advantage of meeting a physician of considerable reputa-

tion as an auscultator. The disease had been pneumonia, supervening, as I believed, upon chronic tubercular disease of the lung, and terminating in rapid phthisis. In the left mammary region there was evidently a large cavity, indicated by tympanitic resonance on percussion, amphoric breathing, and metallic resonance of the voice. The accomplished physician referred to expressed his belief that pneumo-thorax existed. I differed from him in this opinion; but I was induced to do so only because, having had the advantage of watching the case throughout, I had observed the consolidated lung to soften down; the cavity to appear and gradually to enlarge, and because the sputa for several weeks had been those of advanced phthisis, excepting when temporarily increased by a passing attack of bronchitis. The body was not examined after death.

A phthisical cavity, indeed, may be accompanied with all the symptoms and auscultatory signs of pneumo-thorax, and pneumo-thorax only by those of a phthisical cavity. The diagnosis in a vast majority of cases may, notwithstanding, be effected with facility, and in circumstances of difficulty may be assisted by the following considerations. In simple phthisis, the tympanitic resonance, and the metallic tinkling (not common in any form), is very rarely so well marked as in pneumo-thorax, while succussion is so very unfrequent in the former, as never with certainty to have been heard by myself, or as far as my knowledge extends, by any one with whom I am acquainted. Laennec is reported to have heard it on one occasion. In pneumo-thorax the chest is *generally* enlarged; in simple phthisis almost always contracted. In the former affection the patient usually lies on the affected side; in the latter upon either side, or upon the back indifferently. In pneumo-thorax the cavity is commonly at the lower part of the chest; in simple phthisis the chief excavation is almost universally at the upper part.

On the *prognosis* of pneumo-thorax I need say nothing, as I believe in all cases hitherto noticed it has proved ultimately fatal; unless, indeed, the case first related in this paper may be regarded as an example to the contrary. The varying duration of the complaint will be best estimated by a portion of the following brief view of the statistics of sixty-two cases. Nearly half of these have either fallen under my own notice or are recorded in the hospital books; the remainder have been collected from the writings of modern authors, and have in all instances been examined by myself.

Of sixty-two cases of pneumo-thorax there were—

Males	48
Females	14—62

The left side was affected in—

Males	28	} 36
Females	8	

The right side was affected in—

Males	20	} 26
Females	6	

—

62

The age of the patients was under 20 in—

Males	8	} 9
Females	1	

The age of the patients was 20, and below 30, in—

Males	19	} 26
Females	7	

The age of the patients was 30, and below 40, in—

Males	11	} 16
Females	5	

The age of the patients was 40, and under 50, in—

Males	6	} 7
Females	1	

The age of the patients was above 50, in—

Males	3	} 62
Was not mentioned 1 male.		

As the statements concerning the duration of life in the sixty-two individuals whose histories I have examined, were in many instances very indefinite, while in some others, in consequence of the uncertainty connected with the accessory period, it was not possible that it could be determined, the following table is necessarily very defective. I have, however, endeavoured in each case where it was possible to calculate the period exactly, and whenever the duration of the complaint was not to be distinctly ascertained, I have called it "uncertain," or "unrecorded."

Duration of life in sixty-two cases of pneumo-thorax:—

"A few hours"	3
Less than twelve hours	2
Twelve hours, and less than forty-eight hours	4
Forty-eight hours, and less than one week	10
"Some," "several," or "many" weeks	5
One week, and less than one month	4
One month, and less than three months	5
Three months, and less than one year	8
Twelve months (at least, Dr. Houghton)	1
Thirteen months (Dr. Stokes)	1
Three years (at least, Dr. Barlow)	1
Uncertain, or unrecorded	18

62

The treatment of pneumo-thorax.—I have little to say—indeed, I believe there is little

to be profitably said—upon this part of my subject, as little can be advanced in reference to the means of affording temporary relief except what is necessarily general, and as, according to all known experience, no specific plan of treatment can be recommended with a prospect of effecting a permanent cure. Symptoms are to be met as they arise. Gentle means are to be employed for their mitigation or removal. Quiet, stimulants, and nutritious food, or sedatives and even antiphlogistics, general or local, may be required in the ever varying circumstances of each case. No rules can be consistently laid down. No plan of treatment can be with propriety prescribed as universally or even generally applicable.

The only questions, indeed, which admit of discussion, are the necessity, the propriety, and the time of performing the operation of paracentesis.

The opinions, or the practice at least, of almost all modern physicians, appear very nearly to coincide upon these points, and the belief seems now to be common that, excepting for the purpose of affording relief to the distressing dyspnoea, paracentesis is not to be recommended in pneumo-thorax.

In the tables published by the late Dr. Davis, of twenty-nine cases in which paracentesis was performed, the following were the results.—

16 empyema . . .	12 recovered	4 died.
9 pneumo-thorax . . .	none . . .	9 died.
4 hydro-thorax . . .	none . . .	4 died.

Among the cases which constitute the table from which the previous numbers as to age, &c., have been taken, I find that of seven only it is stated that paracentesis was performed.

Of these—

1 died four hours after the operation, and was thereby not relieved.

1 died twenty-four hours after, not relieved.

1 died forty hours after, not relieved.

1 died sixty hours after, relieved.

1 died six days after, relieved.

1 died twelve days after, not relieved.

1 died sixteen days after, relieved.

From these facts, together with those previously mentioned from Dr. Davis, it appears evident that the operation of paracentesis affords not any prospect of effecting a cure of pneumo-thorax, and that in many cases experience warrants but little hope of its affording even temporary relief. When, indeed, it is recollected that in numerous examples the egress of the gas remains perfectly free, it appears difficult to understand upon what intelligible principle the operation, at least in such cases, can be recommended with even a fair prospect of success. A free opening already existing, I must confess my own inability to comprehend why another

should be required. There are, however, three conditions under which I imagine it may possibly be advantageous to perform paracentesis in pneumo-thorax. First, when the accession of the complaint is marked by great anxiety and general distress, arising from excessive dyspnoea; secondly, when, after a considerable duration of the complaint, gradually increasing dyspnoea supervenes, in consequence of the egress of the air being prevented or obstructed by an accidental fold of membrane, plastic pleuritic effusion, or bronchial secretion; and thirdly, when fluid effusion is added to the other effects of the accident, and accumulates in such quantity as materially to embarrass the respiration, and thus increase the distress already existing. In these circumstances, as purulent, or sero-purulent fluid, may require a dependent opening for its exit, the operation may be fairly expected to be followed by temporary benefit.

We may perhaps be allowed hence to state the general law, that in pneumo-thorax proceeding from disease, and not from external injury, the operation of paracentesis offers little prospect of advantage, and is therefore not to be recommended, except for the purpose of relieving urgent symptoms of dyspnoea and anxiety, caused by the accumulation of gas or of sero-purulent fluid.

Much, however, may be done in many instances, as I know by experience, to render the life of the patient easy, and even tolerably comfortable. The *jurantia* and *ledentia* cannot be here specified, as they will necessarily vary more or less with the particular circumstances of each case. Stimulants may be here required, and sedatives may be beneficially prescribed there; but in almost all cases, though we may have the sad conviction that our best-directed efforts cannot save or permanently restore our patient, we may possess the melancholy gratification of contributing, by kindness, by attention to position and diet, and the judicious administration of medicine, to mitigate his sufferings, or to relieve his pain, and thus to procure for him a tolerably quiet and moderately comfortable existence. "Proud science," says Dr. Houghton, with much feeling eloquence, "may draw back from what seems to be beyond her realm; but the physician has higher instincts to obey and duties to perform here, as in other hopeless diseases, in attempting even the mitigation of the pain and anguish which science tells him he cannot altogether remove; and this reflection may be added, that where such motives actuate him to exertion, he is seldom left entirely without the satisfaction which obedience to them brings."

I proceed now to relate a few of the cases which I have seen, and of which I have fortunately preserved or obtained notes.

CASE III.*—Diffused Phthisis—A single small cavity—Pneumo-thorax—Opening not discovered—Death in thirty-four hours.

C. A., aged 22, a weak and delicate-looking woman, of light complexion, came under my care as a patient at the Surrey Dispensary, July 20th, 1839. She resided at Lambeth, was occupied as a sempstress, and had been troubled with weakness and pain of the back for some years, and had attended as an out-patient at Guy's Hospital in consequence. She had not, however, been troubled with cough of any severity or constancy till three weeks before I saw her. She had never suffered from hæmoptysis. Her father was dead; she had a mother, and some brothers and sisters, in good health. At my visit I found her in bed, very feeble, pallid, and nervous. She complained of cough, with tightness of the chest, and rather copious mucous expectoration; the tongue was pale, clean, and moist; the pulse small, feeble, and very frequent; the catamenia irregular, and accompanied with pain. She was so excitable as to prevent any useful examination of the chest by either percussion or auscultation. But from the imperfect exploration I was enabled to make, I believe the signs were those of bronchitis. If phthisis existed at all, the tubercles were generally diffused throughout the lungs. She was at first treated with expectorants and counter-irritants, and subsequently with emetics, and iodine combined with sedatives, and improved so much in a week or two as to take tonics with obvious advantage. About the end of September she had a fresh attack of bronchitis, with considerable febrile excitement. I now thought it necessary to apply a few leeches below the clavicles, and to follow them with a blister to the sternum, and to administer small and repeated doses of antimony, blue pill, and opium. The soreness of the chest was thereby considerably lessened; the cough, however, continued, and her debility was advancing; the pulse, always rapid, had increased in frequency, and emaciation of the face and limbs was perceptible and progressive. In the middle of the night of October the 9th, after a day passed as well as, or rather better than usual, she had a fit of coughing, remarkable neither for its violence nor its duration, which was immediately followed by excessive dyspnoea, accompanied with pallor of the face, clamminess of the surface, and other evidences of collapse, and also with flatulence of the stomach and bowels, but without pain. She continued in this state till I saw her twelve hours after, when I found her lying on the right side; the face and body bedewed with

clammy perspiration; the extremities cold the respiration hurried and anxious, and the pulse excessively feeble and rapid. Any attempt at moving the body appeared to add to her distress, and to endanger her life so much that no efficient examination of her chest could be made, and the only facts ascertained as to its condition were, that the right side was very resonant on percussion, and that the resonance extended behind the sternum. She had no cough, but was still troubled with flatulence. Sinapisms were ordered to be applied to the scrobic. cordis and to the feet, and ammonia and brandy to be administered internally, but they produced no effect. She never rallied from the state of collapse, and expired at 10 A.M. the next morning, about thirty-four hours after the accident.

Inspection 24 hours after death, kindly performed in my absence by Mr. Nettlefold and an assistant.—The head was not opened. On removing the sternum, air escaped with a hissing noise from the right pleura. The lung was reduced to one-fourth its ordinary size, and adhered superiorly to the pleura costalis. It was studded in every part with miliary tubercles, which appeared to have softened in no other situation than in the mammary region, in which existed close to the surface a cavity the size of a nutmeg. The pleura was filled with air alone, contained no liquid effusion, and presented no evidence of recent inflammation. The mediastinum and its contents were pushed much to the left side. No aperture was discovered in the pleura, but the lung was not inflated by the blow-pipe. On the left side the lung was greatly congested, and sprinkled with tubercles, which were generally immature, but were in some parts just beginning to soften. The heart was small and flabby. The abdomen was not examined.

This case presents a very fair example of the effects of pneumo thorax occurring from a lung not extensively diseased, and causing therefore a sudden and almost total arrest of the circulation in one-half of the respiratory organs. The rush of gas which occurred on opening the chest, together with the pressure of the mediastinum to the left side, appears to indicate that the air, after the collapse of the lung arising from its own elasticity, entered in larger quantity, or with greater facility, than it escaped from the pleura, if, indeed, during life it escaped at all, and renders it probable, therefore, that some transient relief at least might have been afforded by paracentesis, which I have ever since lamented was not in this instance performed. The absence of pain, and all indications of pleuritis, the single and small cavity near the surface of the lung, and the complaint of great flatulence of the stomach and intestines, are also worthy of notice, as it has been supposed by some that pleuritis and

* Cases 3 and 4 have been previously published by me in the "Reports of Cases" in the MEDICAL GAZETTE.

consequent pain are among the almost necessary results of the accident, and as I do not remember to have observed that flatulence has been a prominent symptom in other cases.

CASE IV.*—*Diffused phthisis—No cavity—Pneumothorax—Opening not discovered—Death in ten hours.*

A very fine young gentleman, aged 19, of light complexion, whose father and mother were alive and in good health, but one of whose brothers had died from phthisis, was suddenly attacked with hæmoptysis without any previous cough, or other assignable cause. After a fortnight he became apparently convalescent, and went to the sea-side for change of air. When he had been there for three weeks, and while he was apparently without complaint, he was suddenly attacked with extreme dyspnoea, and died in about ten hours.

Inspection, 24 hours after death.—Percussion elicited a remarkably clear sound on the left side of the chest, while the right side was dull, particularly posteriorly. The head was not opened.—*Chest:* On dividing the cartilage of the fifth rib on the left side, gas escaped with a wheezing noise. Two-thirds of the left side were filled with air, the remaining third being occupied by the collapsed lung, the upper lobe of which was adherent to the pleura costalis by old and firm cellular membrane. In every other respect the pleura appeared healthy. The left lung was throughout sprinkled with tubercles, some of which, close to the surface, caused elevations to appear on the pleura pulmonalis, but none were observed to have formed a cavity, or to have caused ulceration of the serous membrane. No aperture in the pleura was in fact discovered, but the lung was not inflated. The right pleura pulmonalis was firmly adherent to the pleura costalis and pericardium. The apex of the right lung contained some immature tubercles. The two inferior lobes were simply congested. The pericardium was firmly adherent to the sternum and to the pleura covering the cartilages of the ribs on the right side and the right lung, and, together with the heart, was pushed upwards and to the right. The pericardium contained rather more fluid than usual, and the heart was flabby and thin. The state of the abdominal viscera was not recorded, if examined.

The only observation that I think it necessary to make upon this case, as the history and symptoms are so defective, is, that it affords another illustration of the severe distress and rapid death occurring after the escape of air into the pleura in cases where

* This case was not seen by myself, but was communicated to me by Mr. Nettlefold, who examined the body, and is introduced here as a rather remarkable example of the complaint.

little, comparatively little, disease exists in the lung, and where, from the opening not having been discovered, it may be fairly presumed, I think, to have been small—a severity and rapidity, however, which, in this instance, was probably materially augmented by the curious adhesion of the pericardium to the sternum and costal pleura.

CASE V.—*Phthisis—Empyema—Pneumothorax—Dulness on percussion—Death in about ten weeks.*

Thomas Davies, aged 28, a tall, thin labourer, of light complexion, was admitted into Guy's Hospital, under the care of Dr. Back, September 18th, 1839. After having suffered from cough, and the general symptoms of phthisis, for some weeks, he was about two months previously to his admission attacked with severe dyspnoea and general distress, without pain, which caused him to desist from his work, and go home to bed. On admission he lay somewhat inclined to the right side, which was not elevated during inspiration, and which to the eye appeared, but upon admeasurement was not found to be, larger than the left. Dulness on percussion existed in the whole of the right side, except just below the clavicle, where the resonance was not greater than natural. In this situation, and close to the dorsal spine alone was heard some bronchial respiration mixed with mucous rattles. In other parts of this side the breathing was strikingly amphoric, and was occasionally accompanied with metallic tinkling. A splashing noise (Hippocratic succussion) was easily produced by any sudden motion of the body. His breathing was not much accelerated, nor was he much troubled with cough; but his pulse was always rapid and feeble. On turning to the left side he expectorated large quantities of sero-purulent fluid. On the left side below the clavicle were heard gurgling and pectoriloquism; the other parts of this lung appeared comparatively free from disease. He lingered in this state about three weeks without any remarkable change of symptoms, excepting that he got gradually weaker, and his lower extremities became œdematous. He died Oct. 8, 1839.

Inspectio Cadaveris.—The head was not opened.—*Chest:* the right pleura was much thickened, covered with a soft, flocculent, albuminous deposit, and contained about forty ounces of thick cream-like purulent fluid. The remainder of this side of the chest, not occupied by the greatly compressed lung, was filled with air, which was, however, not in large quantity, as the mediastinum was not displaced. The lung was superiorly adherent to the pleura costalis, reduced to about one-third its ordinary size, and contained several small vomice, and

tubercles distributed throughout nearly its whole extent. Four of these were situated near the surface, and two of them—one the size of a pea—the other as large as a hedge-gut—communicated through considerable openings with the pleural cavity. The left lung was also adherent superiorly to the pleura costalis, and contained several small vomicae, surrounded by pneumonic consolidation. The bronchial tubes of both lungs contained much purulent fluid; and the larger branches were considerably injected, and slightly granular. The pericardium was healthy. The heart was much dilated, flabby, and thin. This was especially remarkable in the right ventricle, which contained several rounded masses of fibrine, “globular fibrinous concretions,” most of which were not larger than peas or small beans, and were lodged in the depressions of the musculi pectinati, but one of which, situated in the apex, was as large as a walnut; its external surface, smooth at some parts, and at others sending off prolongations, which interlaced with the muscular bands, was in contact with, but not adherent to, a mass of coagulated blood. Its walls were about one-eighth of an inch thick, soft, dull, and opaque. It was filled with an opaque albuminous fluid, having the appearances of pus, but which, though not examined microscopically, I believe, as I have already expressed my conviction in reference to similar cases, to have been merely softened or broken-down fibrine.—*Abdomen*: The liver was large, turgid, and myristicate. The kidneys were also large, and congested. The spleen, pancreas, stomach, and intestines, were not observed to be diseased.

The circumstances in this case particularly worthy of notice are, in the first place, the co-existence of dulness on percussion with most of the other physical signs of pneumothorax. This, which I had myself an opportunity of verifying on several occasions, was sufficiently explained after death by the considerable quantity of semi-solid and fluid effusion in the pleura, by the complete collapse of the lung being prevented by the tubercular deposit which it contained, and by the *accumulation* of air being prevented by its free egress through two openings of considerable size. In the second place I may remark that it is at least a curious coincidence, that in this, and in a case to be subsequently related, a well-marked fibrinous concretion, of considerable standing, was found in the apex of the right ventricle, the situation in which, in consequence of the obstruction to the flow of blood through the lungs, the delay would be the greatest. This obstruction causing delay, together with great prostration of the power of the patient, and consequent feeble action of the

heart, as has been already stated in a paper on “Fibrinous Concretions in the Heart,” in the Guy’s Hospital Reports, is probably the principal, if not the sole, cause of the formation of that modification of these bodies which was observed in the case under review.

For a record of the following case I am indebted to the notes of Dr. Grant, Staff-Surgeon 2nd Class, formerly in charge of the Military Dépôt at Maidstone, and now in India; and to the kind assistance of Mr. Prance, Surgeon, of Maidstone, with whom, together with Dr. Sebbald, of that town, I had an opportunity of exploring the chest of the patient, and of verifying all the principal symptoms and physical signs. Dr. Grant’s notes are very long. I have taken the liberty of condensing them considerably.

CASE VI. — Phthisis — Pneumothorax — Empyema—*No symptoms indicating the accession of the complaint — Extensive tubercular deposit — Death in about two months.*

Wm. Moran, aged 18, of spare habit and scrofulous diathesis, a private and bandman, blowing the opheicleide in the 15th Regiment of Light Dragoons, had enjoyed good health till two months before, when he suffered from catarrh and cough following exposure to wet, and was admitted into the Regimental Hospital, where he stayed two weeks. He then performed his duty for nearly a month, and was sent to the Maidstone station on furlough. After three weeks’ residence he was admitted into the Dépôt Infirmary, January 12, 1841. He then complained of hard cough, with greenish mucous expectoration, oppression of the chest, dyspnoea, debility, and nocturnal perspirations. The left side of the chest was particularly resonant on percussion, and afforded metallic tinkling over nearly its whole extent; pulse 120, and irregular; heart’s action tumultuous. Ordered a blister and an expectorant mixture, with Tr. Digitalis, &c. &c. His medicines were subsequently varied without any obvious advantage or marked effect, except that of procuring sleep.

On January 25th, about the day on which I saw him, little alteration had taken place, and the symptoms were as follow:—Cough pretty frequent, with greenish expectoration; pulse 112, and small and feeble, but distinct; tongue natural; skin soft. He lay on his back, but could turn to either side, or sit up in bed, without increased distress. The left side of the chest was perceptibly larger than the right. Impulse of the heart was felt distinctly and solely on the right of the sternum, and indistinctly below the right clavicle. The right side was dull on percus-

sion; pleuritic rubbing was heard pretty generally, but was most distinct inferiorly and posteriorly. Large mucous rattles were heard below the right clavicle, the respiration was bronchial, and bronchophony was distinctly audible in other parts of this lung. The left side was very resonant on percussion; and the respiratory murmur was entirely absent, excepting over a small space on the inner side of the infra-clavicular and mammary regions, where it could be scarcely heard. Amphoric breathing, metallic tinklings, metallic resonance of the voice, and cough, and Hippocratic succussion, were very distinct about the lower edge of the scapula, and were audible, though less obviously, in other parts of this side.

Ordered Decoct. Cinchone, &c. during the day, and Morphia at bed-time.

I find no circumstance related particularly worthy of notice till the 29th, when it is stated that he passed the night on the right side, and was then sleeping quietly on the left; that the cough was only occasional, and not distressing; the pulse was 130, and very weak; and that the two sides were becoming equal in volume.

Feb. 21st.—He was able to get out of bed and sit up each day; the dullness of the right side had, in a great measure, disappeared; and the enlargement and rotundity of the left had given place to a more natural configuration, the intercostal spaces being depressed as upon the opposite side. He slept well at night under the influence of morphia, and was but little troubled with cough; appetite good.

March 16th.—Went down stairs for half an hour this day.

20th.—Sent for in haste, and found him with hurried respiration, lying on his back; face purple, and extremities cold; pulse not perceptible; dosing, and speaking with difficulty; in no pain, and perfectly sensible; respiration very short, and hurried. He was temporarily rallied by hot brandy and water, and other stimulants, but soon relapsed into the same drowsy state, and wished to be allowed to go to sleep, and in this state quietly sank at half-past ten o'clock.

Inspection, twenty-four hours after death.
—The Head was not opened.—*Thorax*: The left pleura was lined with a firm layer of lymph, one-sixteenth of an inch thick, and contained more than three pints of straw-coloured serum, in which were suspended large flakes of fibrin. The lung was greatly compressed, and lay close to the mediastinum. A small portion of the lower part of the upper lobe was alone crepitant, and corresponded in situation to that part of the chest in which respiratory murmur was sometimes heard during life. The re-

mainder of the lung was occupied either by tubercular deposit or small cavities, some of which contained some soft cheesy matter. One cavity, as large as a small egg, was quite empty, and communicated with the pleura by a circular aperture with rounded edges, half an inch in diameter. It was situated two inches from the summit of the lung, which was firmly adherent to the pleura costalis, as was the base to that covering the diaphragm. The pleura covering the upper and middle lobes of the right lung was adherent by recently effused plastic lymph. About eight ounces of clear serum existed in the lower part of the sac. The upper lobe contained one cavity capable of holding two ounces, and others of smaller size; the remaining portions of the lobe being perfectly airless, from tubercular deposit and grey hepatization. The middle lobe contained a few small cavities; and the lower lobe was crepitant and fairly healthy, independently of cadaveric congestion. The pericardium contained three ounces of serum, and was firmly adherent to the right pleura; it was thus preserved in its situation on the right of the sternum, when all support was removed. The heart was healthy.—*Abdomen*: The peritoneum contained eight or ten ounces of fluid, and, in some parts, bore evidence of recent inflammation. The liver, spleen, pancreas, stomach, and large intestines, presented nothing remarkable. The mucous membrane of the small intestines was much diseased from tubercular deposit and ulceration, particularly towards the termination of the ilium and the ileo-cæcal valve. The mesenteric glands were also much diseased, enlarged, hardened, and, in some parts, contained cheesy matter.

This case presented, with remarkable distinctness, all the ordinary symptoms and physical signs of pneumo-thorax; yet was the patient able to lie upon either side, or upon his back, to sit up in the ward, and, on one occasion, to go down stairs; and though the side was at first obviously enlarged, it gradually assumed its natural size. It is also to be observed, that the formation of the complaint was marked by none of that urgent distress supposed by Louis to be almost its peculiar characteristic. I made inquiries particularly in reference to this subject, but could obtain no information by which it could be ascertained on what day, or at what time, the gas first escaped into the pleura. The lung was greatly diseased; and the aperture was so large that the air could escape from, as well as enter, the pleura with facility. His rather sudden death was most probably connected with a rapid effusion of serum into the cavity.

[To be continued.]

CONTRIBUTIONS
TO
ANATOMY AND PHYSIOLOGY.

BY ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

[Continued from p. 451.]

Hermaphroditism: a Memoir read to the Royal Society of Edinburgh in 1827 and 1828.

SINCE we cannot doubt the existence of hermaphroditic structure; since it obviously occurs in man, and that hermaphrodites are neither deformed males nor deformed females, and that neither the doctrines of a *lusus naturæ*, nor any other doctrine with which I am acquainted, can explain to a rational mind these singular and mysterious appearances, there remains one legitimate subject of inquiry—the investigation of the cause. Some very eminent physiologists have imagined a solution of the causes of hermaphroditism to exist in the speculative views as to the original laws agreeable to which they imagine all animals to be formed or constructed. Hermaphroditism, they remark, occurs in many of the lower animals; and if it be true that man is forced by a law of nature to pass through all grades of formation, should the development of the generative organs, by any accidental cause, known or unknown, be arrested, these organs will remain necessarily at a stage of the development corresponding to some of the lower animals; and hence the origin of hermaphrodites. It is sufficiently singular that, generally, the persons who support this hypothesis maintain also the theoretical opinion, that the male and female organs are essentially the same, being but slightly modified, a theory which the society will remember was easily enough traced back to Galen, if not to Aristotle: its modern dress changes it but little. As I should dislike extremely being misunderstood in the criticism I am about to offer, and should feel sorry at misunderstanding or mistaking the sentiments of others, I shall examine in detail these opinions.

The writings of Caspar Bauhin, which were quoted at great length in the first part of my memoirs, leave no doubt on the mind that the following

doctrines are essentially in all respects the same.

“By supposing the ovum, previous to impregnation, to have no distinction of sex, but to be so formed as to be equally fitted to become a male or female fœtus; and that it is the process of impregnation which marks the distinction, and conduces to produce either testicles or ovaria out of the same materials.” These are the expressions of Sir E. Home, in his memoir on hermaphrodite structure, in the Philosophical Transactions.

Notwithstanding the high antiquity of this opinion, and the support it has received from almost all modern anatomists, there cannot, I think, be a reasonable doubt entertained of its being fundamentally erroneous. So long as the ducts of Malpighi were undetermined, so long as *they could not even be named*, their exact nature might be, and was disputed. Supposed by some to be analogous to the uterine tubes in the kangaroo; denominated, even a few years ago, utero-vaginal tubes, in the first zoological school in the world*; so long the doctrine of analogies and similar organs might maintain a position in science: but it has been shown that these are male organs; that though present in females, exercising all their functions as such, they are essentially, and in all respects, *male organs*; that they cannot be the same as the fallopian tubes, since they are found *co-existent* with these tubes. We cannot surely say of two organs, which can be shown as separate and distinct, that they are essentially the same, and are formed out of the same materials. In the hermaphrodite case submitted to the society, the testes were of the natural size, the vasa deferentia perfect; the animal alternately showed the propensities of male and female, and was obviously capable of acting efficiently as male; but there was present, besides these organs, a perfect vagina and uterus, with slight remains of the fallopian tubes, and perhaps ovaria, though I do not insist on this. It cannot be said, surely, after this, that there is but one kind of organs, out of which the male and female organs are formed; for if reason mean any thing, it assuredly warrants us in denying that, out of exactly the same

* This observation I make whilst revising my original memoir.

materials, two organs essentially distinct can be formed.

(Sixteen years have now elapsed since these remarks have been written and submitted to the Royal Society here; and although the ducts of Malpighi were demonstrated by me to be simply the rudimentary *vasa deferentia* of the male, *persisting in the female*, I still find that anatomists prefer theoretical views in preference to what is as plain a demonstration as any in Euclid. These tubes, as a last resource, have been called the "ducts of the corpora wolfiana" by the compiler of the catalogue of the museum of the London College. To such a view as this there are many heavy objections, the weightiest of all being that these tubes have been distinctly traced to the *testes* in an animal showing all the propensities of male and female (1843).

Perhaps it may be said that we cannot reason about the unnatural or hermaphroditical appearances, because there may be extraordinary deviations from nature's laws. I do not myself perceive the force of this: I observe an animal to become more and more equivocal in its generative organs, as both kinds are found to persist in it in a more and more perfect condition; when the appearances of hermaphroditism are few and unimportant, the effects upon the œconomy are insignificant; if extensive, they convert the animal into a new being. The reason for all this seems to depend on this great law in the construction of the genital organs: the embryo is at first hermaphroditical, both sets of organs are present: if the cause determinative of sex should act in an efficient manner, one set of organs nearly disappears, and the fœtus becomes male or female; but if not, nature adheres to her original type, and both kinds of organs remain: "the type of the generative organs even in the highest orders of animals is hermaphroditical."

Before I proceed to bring forward the proofs (in so far as my time permits me to do) of this theory, it seems right that I should notice the opinions of others.

In a very recent work on philosophical anatomy, the male and female genital organs are considered as simple modifications of one type: the uterus represents the prostate and seminal vesicles by its position, form, and functions: and yet in the free-martin de-

scribed by Mr. Hunter, and in the human hermaphrodite of M. Petit, of Nemur, the seminal vesicles and uterus coexisted.

M. Meckel supports the doctrine that all embryos are of the same sex at their origin; and he states the analogies to be—

Testes	Ovaria.
Fallopian tubes	Vasa deferen.
Vesic. semin. and prostate	Uterus.
Penis	Clitoris.
Vagina and nymphæ	Penis&ureth.
"qui sont restées en dedans, au lieu de faire saillie au dehors."	
Greater labia	Scrotum.
Mammæ	Mammæ.

But it is not the German school alone which supports these ideas of the ancients, which have adopted them as their own, unfolding, as they have imagined, the rather vaguely expressed notions of the older anatomists, though this pretended vagueness may be merely supposition, and not supported by an appeal to the writings of Gal n, of Fallopius, or Caspar Bauhin: theories altogether similar are maintained by very exact anatomists of other countries. The *Bulletin des Sciences* for 1815, p. 155, contains an exposé of the views of M. de Blainville. According to this gentleman, the organs of generation are originally of the same nature in every degree of the organization, composed of the same parts, and this nature is evidently female; the male sex being simply a modification of it.

It is supposed, also, that in the animals called actinomorpha there is no male.

In certain mollusca one side is male, the other female.

This kind of hermaphroditism is supposed to exist in fishes, and to be efficient.

But again, it is said that animals are born neuter (*Les animaux sont produits avec le même disposition d'organes de la génération.*) "Ils sont pour ainsi dire neutres, et ce n'est que par la suite que de circonstances qui nous sont entièrement inconnues font rester l'individu femelle, ou le font passer à l'état de mâle."

All doubts as to the author's meaning in the passages cited (if any doubt could be entertained) are removed by what follows.

"The ovary in the female is represented by the testis in the male." M. de Blainville next compares the scrotum to the nymphæ, the fallopian tube to the vasa deferens; the epididymis and seminal tubes are represented by the broad ligaments of the female. This, also, is Rosenmüller's opinion, whose works, however, I have been unable as yet to procure, so that I cite the name of this exact and distinguished anatomist on the authority of others: the seminal vesicles are compared by M. de Blainville to the uterus, and the clitoris to the penis. These opinions are, as we have already shewn, nearly 2000 years old.

Theories such as I have now cited are at variance, as it seems to me, with all well-observed facts: if both kinds of organs are found to coexist in the same individual, they cannot be formed precisely out of the same materials.

M. Meckel distinctly claims to himself the having first demonstrated ("démontrée d'abord, par mes propres recherches,") the idea that the organic deviations consist in a stationary condition of the development, rendered fixed at a degree of formation anteriorly normal or regular. He allows that it was suspected by Harvey, and afterwards by Wolfe and Autenrieth, and finally adopted by Reil, Tiedemann, Chaussier, Beclard, Blumenbach, Blainville, Heusinger, and Leuchardt. But it seems to me impossible to explain, on these principles, why an organ should run from a more complex to a more simple type; and the calling that a non-development of any organ which actually consists in the persistence of a more complex structure than what was contemplated by nature, seems to me an inconsistency in terms. Why should the type of almost all the organs be so complex in the lower animals, and of many of them so seemingly simple in man? and why should the elements of these complex types and organs be visible in man in the fetal state, and their traces discoverable in the adult? It is because there is one type for all, and all animals were contemplated as coming within the range of this type.

The 143d section, page 598, of M. Meckel's work on Comparative Anatomy, has satisfied me that he has no clear ideas of the cause of hermaphroditism. Again, at Sect. 142, we find the following remarks:—cases of herma-

phroditism may be reduced to an original absence of sexual difference, to the analogy which exists between the male and female organs. Finally, they may consist in a re-union of the characters of both sexes, in the same individual. Such, he says, is his opinion, and such also, he says, is the opinion of Ackermann, Buzdach, Stiglehn, Scillan; but so far as I have understood Stiglehn, this is not his opinion, and it will be easy, if necessary, to quote passages from Stiglehn's works in which he arrives, in as far as I may judge, to nearly the same conclusions that I have myself drawn; but as his work is full of strange contradictory passages, and, at the same time, deeply tinged with a philosophy, or rather, I should say, system of metaphysics which, to me, and, I believe, to most persons in this country, is quite mystical and positively unintelligible, I shall not particularly insist on this point; at the same time, it must be admitted that this passage, summing up, as it were, M. Meckel's opinions, is sufficiently obscure.

"The masculine sex is a degree of development more elevated than the female. (Page 541).

"All the embryos of the superior animals are, in fact, formed after the same type, which is the type of the female. Even when the sexual difference is already developed, the male fœtus offers still analogy with the female; it consists in the position of the testes, which have not yet quitted the abdomen, and of that of the orifice of the urethra still situated upon the lower surface of the penis."

Now, if these passages be compared with what M. Meckel has said formerly, they will be found to be completely at variance. "We must not forget," he continues, "that the character proper to the species develops itself betimes."

But let us admit that the first rudiments of the species the most different are essentially the same.

At page 530, he speaks of the absence of all sexual difference which takes place primitively in all the superior animals.

M. Meckel further says that the principle of the reduction of the hermaphroditic formations to the regular type, is founded on the "communauté" of a fundamental type between the generative type of the two sexes, that is to say, on the absence and the de-

iciency of the primitive difference. Hence it results that the anomalous dispositions of the superior animals are regular in the more imperfect organisms.* But it seems to me exceedingly difficult to understand how he should ascribe to a primitive deficiency the absolute presence of two sets of organs in the same individual. An absence of primitive differences is far too vague a term even for physiology.

"I have already said, page 678, that the genital organs of the two sexes are primitively constructed upon the same plan, that they are to be considered only as modifications of the same fundamental type. In fact, it is easy to demonstrate that all the parts which by this re-union constitute this apparatus exist equally in both sexes where they differ only in relation to their volume, structure, and situation; all embryos are of the same sex in the beginning; the testes correspond perfectly to the ovary with a reference to configuration, functions, vessels, and nerves."

"The fallopian tubes are evidently analogous to the vasa deferentia. It is probable that in the beginning they communicate with the ovaries by straight tubes, and by a sort of epididymis like what exists in man. The seminal vesicles and prostate correspond undoubtedly to the matrix, only the matrix is larger, and more completely developed."

"The penis and the clitoris resemble each other. This analogy requires to include the vagina and the nymphæ."

"The greater labia represent the two halves of the scrotum.

"Until the sixth week, there is no trace of genital organs; at the moment of their appearance they are formed absolutely of the same type in all embryos; their form, their volume, their situation, are the same (p. 654), and consequently there is no distinction of sex.

"The internal genital parts are composed of two considerably elongated straight parts, oblique from without inwards, and from above downwards. These are situated high up out of the pelvis, and become afterwards either testes or ovaria."

"Secondly, two canals almost as broad as the parts we have just spoken of, but which are longer and thicker, extend beyond them upwards, and descend on their outer side; they produce

either the fallopian tube or the epididymis and vasa deferentia; and they unite external to the pelvis, in a common median duct, which becomes either the womb and vagina, or the prostate gland, seminal vesicle, and posterior part of the urethra. Thirdly, of a considerable body, triangular, somewhat swollen at its anterior extremity, formed of two halves separated by a furrow proceeding along the lower surface, and becoming ultimately clitoris or penis.

"The folds found on each side become ultimately either the scrotum or greater labia.

"This original identity of the genital organs in all individuals was perceived by Home, Autenreith, and Akermann."

The original type of the generative organ in all animals seems to me hermaphrodite; but neither did she intend that the adult animal should grow up so in all species of living beings. In the vegetable kingdom, perhaps, we have a hermaphrodite perfect in all

* Notwithstanding the dogmatic manner in which these remarks are made, as to the strict anatomy of the embryo organs, there is every reason for believing them generally incorrect. I have not myself been able to make out, in a way altogether satisfactory, both sets of organs in the male fœtus; and although the gubernacula obviously are the round ligaments, and consequently, then, that at an earlier period the elements of the uterus may also have existed, I cannot say that as yet I have been able to determine this satisfactorily. In the examination of the female fœtus, it is easy to see the remains of the testes; this structure, which I think must have been seen by most anatomists, was probably first described by Rosenmüller; its nature was altogether mysterious to me until the period of these late observations. M. Meckel's remarks on this structure are as follows: "Between the fallopian tubes and the ovaria in a fold of the peritoneum there are found, not only in the embryo and fœtus, but even a short time after birth, vessels extremely remarkable, which since they can neither be injected from the ovary nor fallopian tube, so that one cannot yet consider them as establishing a communication between the cavity of the tube and the substance of the ovary, resemble exceedingly the vasa deferentia of man with regard to number, situation, and form, that one might see in them a tendency to the formation of these canals and of the epididymis."

But the form which the abdominal extremity of the tube affects in the origin, allows of this very probable conjecture, that these vessels are the means of communication, at first, between the fallopian tubes and the ovary; but that this communication becomes effaced, probably at the time when the abdominal extremity of the fallopian tube opens, and when there forms consequently a new road or passing.

These appearances, I repeat, I have frequently seen; and feel assured that the peculiar vessels, or appearances of vessels, are simply the remains of the male testes, epididymis, and vasa deferentia, in the female embryo.

respects, and the production of an individual without the concurrence of two; for wise purposes, without doubt, nature has disjoined the sexes in some, uniting them in others; but the original impress, the preconceived plan, cannot be mistaken, and when she deviates from ordinary structure, the return is always to the original type. To me, then, it appears, that in the construction of animal bodies, an original type has been contemplated in the forming each great system of organs, and that she has not proceeded from the more simple to the more complex, adding structures as they might be required, nor yet has she selected any particular animal as a model for all the rest. The doctrines of "formations arrêtée," and the superaddition of parts and systems of organs as animals ascend in the scale of being, has no foundation in truth, or at least must be included in a broader generalization. It may be, perhaps, pushing a metaphysical abstraction too far, to assert, that in forming any organ, or series of organs in any animal, all the complex elements which the same organ may present in other animals are also present in the more simple, but still I believe this to be the case. Though the human cranium be in the adult state composed but of eight bones, it is essentially constructed out of a series of bones as numerous as those of the cranium of the crocodile, or fish; nor could this have ever been imagined by any one *à priori*; the proofs have flowed from direct inquiry into structure. The bones of the human shoulder, which seem so simple in their adult state, may yet be proved to be very complex when young, and to possess all the elements, all the original germs or centres of ossification, which ultimately as separate bones are found to compose the shoulder of the echidna. I do not mean to say that the skeletons of these animals were the original type laid down by nature in the execution of her great plan, but without doubt the type of the skeleton of all the vertebral kingdom is not so simple as in man, but extremely complex.

If we apply these views to other organs, we still find support from their arrangement. Two objects seem to have been contemplated in the construction of animal bodies; the performance of function, as regards in-

dividualism, and the providing for or contemplating all possible existing forms of animal bodies. The number of component elementary parts, then, are the same in all the organs, and this accords better with those ideas which naturally flow from a close observation of nature's plan; viz. that the mind which contemplated, and the idea which fashioned the living animal kingdom, foresaw all things, all possible combination of forms, and whilst the species of animals were determined by fixed laws, thus giving to each kind its own special secondary type, one great elementary structure was made to pervade all. Whilst the supporters of the doctrine of analogous organs and "formations arrêtée," are attempting to shew the analogy between the component parts of the lungs and of the gills, fancying them to be the same organs because their functions are similar; the similitude, nay identity, of the osseous branchial apparatus with the ribs, or with the pulmonary tubes of the animals which breathe by lungs, meeting insurmountable objections and obstacles to their theories, and forced to alter and amend their views daily, as new facts are discovered; whilst they cannot even name the bones termed branchial arches, calling them sometimes ribs, though they must know that fishes have ribs in their proper place and usual situation, and sometimes os hyoides, being uncertain as to their real nature; whilst they are unable to determine the nature of the so-named swimming bladder, and fancy it to be some how or other connected with the ear; a single phrase seems to me to solve these questions; the lungs and gills are not the same; they are not formed of the same materials; the type of the respiratory organs in all vertebral animals is at once pulmonary and branchial. Nature foreseeing that certain vertebral animals would live well by lungs, others by gills, and that some would require both, gave a type to meet all; that type is complex: all animals originally possess both gills and lungs*.

If proofs were wanting in support of

* (1843.) This bold hypothesis was thrown out by me in 1827, as may be seen by the text. At that period the dissections of Rathke, which proved my theory to be the correct one, were unknown in this country. My own views were, I admit, derived principally from theory, but that theory has since been proved to be the real and only admissible one.

this view, I might instance the hyoid bones and ribs being present and co-existing in so many animals; the anatomy of the proteus, which possesses both organs, and seems to use them both alternately; of the syren, and azolotl; the growth and œconomy of the tadpole, and of all reptiles; the presence of both organs in fishes, though they are not both required; the air cells in the abdomen of the diodon; and lastly the presence of gills in the chick at an early period of its incubation, which I have not myself seen, but which is here brought forward on the authority of Baer, and of other anatomists of the German school.

An original type seems, then, to have been contemplated for each organ or assemblage of organs; that type generally, so far as I have yet been able to observe, is extremely complex, and embraces within its range all possible structures: no particular animal has been selected as offering within its structure the types of all the organs, the œconomy of some low in the scale being very complex as to certain organs, and *vice versa*.

But wherever the type may be found, we shall generally find the rudiments or elements in other animals, indicating that these organs, simple in their appearance, were yet originally contemplated on a complex plan: who, for example, looking at the adult scapula of one of the higher mammalia, could believe that it was really composed of so many different elements capable of assuming a degree of importance as distinct portions or bones, wherever the peculiar œconomy of the animal, whether higher or lower in the scale, required this arrangement to take place? But if this happens with parts of so gross materials as the bones, if their structure should require such careful observation, it cannot reasonably be expected that the same degree of nicety in research and proof by demonstration should be made out in regard to organs formed of soft and rapidly absorbed materials. The size of the thymus, or of the supra-renal capsules in the fœtus, could not be anticipated by an inspection of these parts in the adult: the total disappearance then of the original elements of organs at an early period of fetal life cannot be deemed extraordinary. To some it might appear a confirmation of these doctrines, that Stegheier seems to conclude, in his

work on hermaphrodites, that the type of all animals is hermaphrodite; but though I have given some considerable attention to his work, I cannot discover his precise meaning, nor the means by which he arrived at this conclusion, if it really be his opinion. He has thought fit, after the manner of his school, to go back to the origin of all things, to the microcosm and macrocosm; to the *omnia in omnibus*; and the nidus for mativus, &c.: there seems no occasion for all this. I ask a plain question. What is the use of certain organs and parts found in the human body and the bodies of animals? and I am told that nature had erred by excess, says one; by defect, says another; it is a mere lusus, says a third; it is normal; it is the perfection of all things. Of what importance, or utility, can it be to any one to be told that, utroque factore in generationis actu ad indifferentiam erecto per formationem embryonis nova oppositio oritur; and yet after all, notwithstanding this neutralization, the product is a being in whom the chances are as a thousand to one that one or other sex predominates.

I have often thought that certain organs found in the mammalia, with whose functions we are not acquainted, and which seem to have a reference neither to the adult nor fetal condition, nor essential to individual life in any known animal, may be the remains of the organs required by that portion of the animal kingdom which has ceased to exist. In the composition of the skeleton of the antediluvian Sauria, unusual combinations of structure are obvious; arrangements and forms of bone, with dimension and shapes, not only not familiar to us, but evidently of a nature differing widely from the present animal kingdom. It will be looked on, I fear, as too bold a flight of the imagination to conjecture that the plan of the present creation was included in the former; that the unexplained organs in animal bodies, and which are in us rudimentary, and so far as we know useless, were once developed, and formed, perhaps, important organs, in a race of animals which ceased at a time when the earth's surface became unfitted for their support.

ISCHURIA RENALIS.

To the Editor of the Medical Gazette.

SIR,

I ENCLOSE a communication read to the Physical Society of Guy's Hospital, on the subject of ischuria; thinking that the case described presents some points of interest, and may not be unsuitable for the pages of your valuable journal.

I am, sir,

Your obedient servant,

THEOPHILUS THOMPSON, M.D.

Physician to the Northern Dispensary, &c.

3, Bedford Square,
Dec. 30, 1813.

There is perhaps no secretion the suppression of which so rapidly induces formidable symptoms as that of the kidneys; and, happily, the occurrence of complete anuria is not frequent. Morgagni had no opportunity of inspecting a single victim to this malady. Sir Gilbert Blane, notwithstanding the great extent of his practice, according to the statement made in his "Treatise on the Prevalence and Mortality of particular Diseases," saw only two examples of the complaint; and the recorded instances are still few and incomplete. Although renal affections have of late been studied with increased attention, there remains much mystery in the relation between the urinary secretion and various functions of the body. In cases of anuria, independently of variations attributable to the degree of rapidity with which the poison of urea may enter the system, there are differences in the effects produced by its introduction, perhaps referable to the variety of individual susceptibility to its influence; and in the present state of our knowledge, it is unquestionably desirable to record every case, the details of which may tend in any measure to illustrate the phenomena of such affections.

An unmarried lady of energetic habits, aged 45, who had for five years suffered in the region of the colon from frequent and severe attacks of pain (which, from the coincidence of tenderness with flatulent eructation on pressing near the sides of the lumbar vertebrae, I was inclined to attribute to a blow formerly sustained on the back), six months after the cessation of the catamenia had a feverish attack, attended with shivering and pain, and

followed by a red eruption, diffused over the body in isolated patches, but regarding the nature of which her medical attendant would not hazard a decided opinion. A few days after the disappearance of the eruption (Jan. 22, 1840), Dr. Daniell, of Bath, who was consulted, found both tonsils inflamed, and one of them ulcerated. There was occasional sickness, but no pain or tenderness of loins. Prussic acid was administered in the "mistura cardiaca" of the Bath Hospital; and the alvine evacuations being offensive, alterative doses of mercury and mild laxatives were also administered.

The sickness continued, and on the 28th of January, the urinary secretion, previously undisturbed, was found to be suspended, so that only half a drachm was obtained on the introduction of the catheter. Nine ounces of blood were removed from the loins by cupping, and small doses of tincture of cantharides administered. In the evening two drachms of turbid urine were passed.

On the 31st, after a few doses of creasote, the bowels were slightly relaxed. The sickness, which had been for a time interrupted, soon returned. The matter vomited was at first sour, and mixed with mucus; subsequently free from smell, and of a greenish hue. Cupping in the lumbar region was now repeated, and eight ounces of blood withdrawn.

When I was summoned from town to see the patient, on the 1st of February, she had passed no urine since the 28th of January, and she suffered from retching, which occurred spontaneously at intervals of about an hour, but could also be produced at any time by compressing the abdomen or loins. The conjunctivæ and cheeks were slightly yellowish; there was some redness and enlargement of the right tonsil; swelling over the jaw, partly glandular, partly œdematous; and slight tenderness in the abdomen and right side of the loins. The pulse 80, rather sharp. The patient's manner was perfectly calm and collected, and I could not ascertain that the brain was in any degree affected, excepting that she mentioned, in answer to particular inquiries, that her sight was rather indistinct, and that she had several times imagined figures before her. We prescribed a spermaceti draught, containing a drop

of Scheele's prussic acid, every three hours, and a bran poultice to the abdomen.

The next day, February 21, the sickness had nearly ceased; the evacuations were less frequent, and contained less mucus. We advised the use of a warm bath, the repetition of prussic acid, and the application of two blisters to the loins. The skin became moist after the bath. One of the blisters was dressed with veratria ointment, in the proportion of a grain to three drachms of lard; but a burning sensation resulted, so distressing as to render it expedient to substitute an ointment of acetate of morphia. This application, although in the first instance followed by an increased sensation of burning, soon afforded material relief. At 8 p.m., after complaining a little of giddiness, the patient passed three drachms of turbid slightly alkaline urine, of sp. gr. 1.019.

Feb. 3d. — She was collected and cheerful, had slept a little in the night, but had vomited once. Two healthy evacuations had been produced by a linseed enema, but no urine had passed. There was some deep-seated uneasiness in the left hypochondrium, increased by coughing. Prussic acid in saline mixture was continued, and a bran poultice applied to the abdomen.

Having ascertained that an issue in the loins, which had been kept open for nearly two years, had healed during the feverish attack, and thinking it not improbable that this circumstance might have exerted an influence on the state of the kidneys, we directed the free application of nitrate of silver, with a view to restore the issue. In the evening a drachm of turbid urine was discharged.

4th. — During the night three successful attempts were made to pass urine, of which three ounces and a half were discharged, turbid and fetid. The appetite was keen; face less swollen.

On returning to London I left the patient in the care of Dr. Daniell, who favoured me with occasional reports, of which I now avail myself.

6th. — Five ounces of urine passed yesterday, and three during the night: it was of brown colour, and highly offensive, but its specific gravity only 1.014; and my friend Dr. Rees, who obligingly examined a portion which I sent him, found it to contain only the

average quantity of urea. There was some giddiness and heat of head, apparently increased by the warm bath; but the tongue was clean, skin moist, œdema of face much diminished, and there was no return of vomiting. The head was shaved, and decoction of wintergreen substituted for saline medicine.

7th. — After the hip-bath complained of a "binding and shooting" pain in the region of the bladder, which was relieved by poppy fomentation. Ten ounces of bloody urine passed during the night: this secretion continued mixed with blood till February 9th. The average daily quantity was ten ounces, and the specific gravity 1.013, till February 12th, when it ceased to be fetid. At this period the œdema of face had entirely disappeared. The quantity of urine gradually increased, and at the end of the month averaged two pints in twenty-four hours. On the 8th of March its albuminous character disappeared, but the specific gravity continued low. The patient gained strength and proceeded favourably till the 11th of March, when she was attacked with the prevailing epidemic influenza, which occasioned soreness and irritation of the mouth and windpipe, cough, heat, restlessness, furred tongue, and occasional vomiting. The expectoration, for two days considerable and mixed with blood, subsequently became copious, mucous, and of a chocolate colour. On the 15th of March the expectoration was diminished, and the tongue moist, but the strength was reduced, and the urine contained blood. On the 17th the patient's manner became restless, her respiration much hurried, skin hot, and tongue parched and furred, but her intellect remained clear. Various measures were adopted, but in vain; effusion was obviously advancing in the chest. At 4 p.m. the pulse was scarcely perceptible, and she sank soon afterwards, not speaking, but remaining sensible to the last.

On an inspection, which was obtained three days after death, some effusion was found in the right pleura. The middle lobe of the right lung was hepatised. The lower lobe of the left lung not hepatised, but tubercular, and extensively attached to the chest by firm adhesions. The heart flaccid and soft, but otherwise natural. The left

kidney was small and flaccid, but its pelvis considerably dilated. The right kidney enlarged. In other respects these organs presented no very obvious change, excepting that Dr. Daniell thought he could detect a slight degree of mottling. The rectum was not distended, and the colon was free from obstruction. The head and spine were not examined.

REMARKS.—The case now recorded is an unusual example of complete interruption of the renal secretion, unattended with the urgent symptoms which protracted anuria usually induces.

In a considerable proportion of instances, as in those described by Sir H. Hallford, (Essays and Orations) Mr. C. J. Hall,* and others, death has occurred within three days from the commencement of the suppression; and Dr. Prout considers five days the limit within which coma is almost invariably established. Nearly all cases of ischuria renalis said to be longer protracted, are probably either referable to deception, or associated with calculous deposit, as instanced by Dr. Clarke†, or dependent on some peculiarity of anatomical structure, as in the case described by Dr. Richardson (Philos. Trans. 1713).

In the present example no urine was secreted for the space of about 120 hours. During the subsequent 48 hours, only half an ounce was passed, and the natural quantity was not restored till after the expiration of a month from the period of its interruption; nevertheless no urgent cerebral symptoms at any time occurred. It may, indeed, be alleged that, in some such cases, according to the statements of Nysten,‡ Valsneri, and others, the fluid vomited or otherwise excreted has contained urea and uric acid, and we can conceive that the overcharge of the blood with urea might thus in some degree be obviated, but in the present example no urinous odour was detected in the matters discharged, and as a general rule, in cases of ischuria, it does not appear that vomiting and diarrhoea have averted or retarded the occurrence of coma. Indeed, we have

no conclusive evidence of the transference of the urinary secretion. The cases adduced by Marangoni,* Nysten, and others, in support of such a doctrine, are unsatisfactory in the extreme.

A circumstance in the present narrative to which I am inclined to attach some importance is, the decided amendment which followed the application of nitrate of silver. My impression regarding the power of this remedy is not indeed derived simply from this solitary instance, but is confirmed by the observation of its efficacy in some analogous cases; in one of which recovery followed its adoption, notwithstanding the existence of decided coma. The final result of this patient's illness, succeeding apparent convalescence, corresponds with a doctrine derived from recent observations, namely, that individuals who have been affected to any extent with disease inducing albuminous urine, are peculiarly susceptible to the influence of epidemics, and are less capable of encountering such incidental disorder.

Irrespective of this contingency, the present case is not discouraging. It confirms my opinion of the appropriateness and efficacy of cupping, issues, and the warm bath, without, however, lessening my distrust of internal medicines, such being excepted as, by their soothing effect on the intestinal mucous membrane, may tend to support the general strength, and may thus by sympathy influence the kidneys.

In acute attacks of ischuria, depending on inflammation of both kidneys, bleeding may be very efficacious. In more chronic cases, unassociated with feverish action, issues may be essentially useful. In all instances the warm bath and demulcents are appropriate, but there may doubtless remain conditions in which the resources of medicine will prove unavailing, and we may still adopt the words of Heberden in reference to this disorder. "Non est dissimulandum, licet pauci quidem his auxiliis visi fuerint servari, alios tamen iis omnibus frustra usos esse."

CASES OF PARALYSIS.

To the Editor of the Medical Gazette.

SIR,

If you think the following cases of sufficient interest, you will oblige me by inserting them in your journal.

I am, sir,

Your obedient servant,

D. DETZERDT HOVELL.

Five Houses, Clapton,
Dec. 18, 1843.

*Case of Paraplegia, treated successfully
by tonics and galvanism.*

In the spring of 1840, C. J., of lymphatic temperament, and not of a very robust constitution, was attacked with ptosis and amaurosis of the right eye, for which he applied successively to three medical men, all of whom gave him mercury, rather freely, but without producing salivation. After this treatment had been pursued some months the ptosis was relieved, but the eye became amaurotic. He became affected with carbuncle, and his general health began to give way.

In March, 1841, I was requested to see him, for the purpose of drawing off his water, and found him in bed, suffering from paraplegia with retention of urine and incontinence of feces; the paralysis was complete, sensation and motion being extinct below the second or third dorsal vertebra. This state had existed six weeks, and in addition to other evils a false passage had been made in attempts to pass the catheter. He had a large moxa on the loins, and a sloughing sore on each trochanter; he was much emaciated and depressed in spirits as well as constitutional power; thought recovery was hopeless, and looked forward to death as the only relief to his miserable condition.

Having cheered his spirits by assuring him that recovery was not impossible, I proceeded to improve his health by generous diet, and by giving internally quinine and iron combined with dilute sulphuric acid; as his nights were sleepless, a third of a grain of morphia was given every evening at bed-time. A hydrostatic bed was procured, which, in addition to rendering him more comfortable, prevented further extension of the sloughing. In the course of the next month he had

much improved in condition and strength, and the effect of strychnia was next tried, but without benefit. At this time the only sign of vitality in the legs was occasional involuntary convulsive twitching of the muscles. Galvanism appeared to promise the best chance of restoring the use of the limbs, and I accordingly began to apply it by means of an electro-magnetic apparatus daily, or as nearly so as was practicable. The parts selected for the application of the poles of the battery were the hollow spaces behind the internal malleoli over the posterior tibial nerves. The first few days no effect was produced, but one morning he told me with great glee he could move his great toe; he soon after acquired the power of moving all the toes, then of flexing and extending the foot, and so on till he could move the whole limb. The motive power was not sufficient at first to overcome the weight of the limb as it lay on the bed, but when it was raised by the hand he could flex the leg and thigh, and extend them again. By this time the control of the bladder and rectum was in some degree restored also, and I next passed the electric current more directly through the parts by attaching one pole to the end of a catheter introduced into the bladder, and the other over the sacrum. In one respect the effect of galvanism was very striking: before its use the muscles of the leg were thin, wasted, and flabby; they now became considerably enlarged, firm, and even hard. During its immediate influence constant and strong muscular contraction took place. It had now been applied more than seventy times, and on an average about three quarters of an hour each time, and the patient had gradually recovered sufficient power to be able to walk a step or two, when supported by a person on each side.

About this time, four months from the commencement of my attendance, circumstances occurred to put a stop to our proceedings, and as he shortly after went into the country, the treatment was not resumed. At the present time he is able to walk a mile with the assistance of a stick only, and says with rest he could walk two; his health is much better than it was for years previous to his illness. The control of the bladder and rectum is not perfectly restored, but he is able to go to church, and to visit

his friends, without fear of accidents. He is able to ride on his pony: this he does frequently. I should mention that six years before the occurrence of paraplegia, and six months after his marriage, he had an attack of hemiplegia, from which he recovered perfectly.

Case of paralysis of the right inferior extremity from injury to the back—Recovery.

John Dehalsted, a fine young man, æt. 21, was admitted an in-patient of the London Hospital, under the care of Mr. Scott, on the evening of the 31st of January, 1838, in consequence of having fallen from a height of fourteen feet into the hold of a vessel, and struck his head against a bar of iron: he complained of soreness over the left temporal muscle, where there were some marks of severe contusion, also of great pain in the back, especially over the seventh cervical and three superior dorsal vertebræ; percussion in the course of the spine did not occasion pain in any particular spot. He felt also considerable numbness in the right lower extremity; sensation remained in the limb, but all power of motion was lost. He passed a restless night, and complained the next morning of great pain in the lower part of the chest, shooting, as he expressed it, to his back; there was some degree of fever, with hot skin, &c.; the pulse was slow, small, and laboured; he was bled to sixteen ounces, forty leeches were applied to the spine, and saline antimonial medicine prescribed; he had also retention of urine, which was drawn off by catheter.

9 A.M.—He has moved the right leg partially, but involuntarily, not having yet any voluntary power: on tickling the sole of the foot, the whole limb is spasmodically contracted, clearly illustrating the excito-motory action, independent of volition. The next day he passed a little water, and the fever had somewhat abated. Ordered—

Hyd. Chlorid. grs. ij.; Pulv. Ipecac.
Comp. grs. ij 4ta. quaq. hora.

Feb. 3.—More leeches were applied to the spine; he continues to pass urine; the contraction of the muscles on tickling the foot has in a great measure subsided, but the paralysis still continues. To continue the calo-

mel. An abscess had formed over the left temporal muscle, where there had been some contusion. Mr. Scott made an incision with a scalpel, and evacuated pus mixed with coagulated blood and serum.

Feb. 6th.—Is much better; the mouth is slightly affected: to discontinue mercury.

On the evening of the 8th he became delirious, and so violent that he could with difficulty be kept in bed; his pulse was feeble, and his extremities cold. He took forty drops of laudanum in a glass of wine, but almost immediately rejected it from the stomach. Mr. Hamilton prescribed a grain of morphia every two hours till he should become quiet. After the fourth dose he fell into a profound sleep, which lasted till the middle of the next day; delirium returned slightly the next evening, and was again subdued by morphia. From this time he progressed steadily and satisfactorily, and was discharged on the 10th of April, having recovered the use of the paralysed limb, with the exception of the great toe. Subsequently he came to the hospital with volition and former power completely restored.

About the same time I admitted another young man into the hospital, under the care of Mr. Scott, who had fallen about seven feet from a ladder, and received a blow over the four or five superior dorsal vertebræ. He complained of pain in this situation, and on examining the chest I observed that the thorax remained passive and motionless during inspiration and expiration, from paralysis of the intercostal muscles; respiration being carried on principally by the diaphragm and abdominal muscles. No other paralysis was discovered. He was treated by general and local bleeding, and the exhibition of mercury. He recovered after a few days.

Paralysis in the first case appears to have depended on general debility, and an unhealthy, probably anæmic condition of the spinal cord, a state analogous, perhaps, to incipient ramollissement, and incompatible with the condition of the medulla—that of generating nervous influence. The repeated and continued exhibition of mercury for some months previously contributed in my opinion to bring on the disease. If we consider one effect attributed to

mercury, that of rapidly destroying red blood, this appears more than probable. The marked good effects of quinine and iron in this case may perhaps be allowed, in support of the theory of Liebig, that these, and other medicines of the same class, act by supplying some constituent or elementary principle that is deficient in the brain or spinal marrow, and at the same time necessary to its healthy and normal condition, and to the exercise of its function. The debilitated state of constitution depending on the "phosphatic diathesis" is readily to be accounted for by the loss to the system of some valuable constituents excreted in the urine, and the readiest, and indeed only method, of curing the disease, is by preventing the escape, or further, by artificially supplying the deficient principle.

Mercury, again, was, I have no doubt, instrumental in effecting recovery in the other two cases, and would appear to be generally indicated in paralysis from accident, where recovery is not spontaneous. In chronic cases of paraplegia, and other forms of paralysis, the diagnosis and treatment depending on it is more difficult. Dr. Farre has expressed his opinion, "that mercury is always indicated when paralysis occurs in persons who exhibit a tendency to inflammation of serous membranes, with deposition of lymph, and that in these cases its extensive use is required." Where there exists a debilitated state of constitution, with anæmia, and a congestive rather than a plethoric condition of vessels, galvanism and electro-stimulant medicines, together with tonics, promise most success.

It is fair to infer that the paralysis in the last two cases was caused by concussion of the medulla, at or near the origin of the nerves supplying the affected parts.

NERVES OF THE UTERUS.

To the Editor of the Medical Gazette.

SIR,

I HAVE been surprised to see the following paragraph in a note by Dr. Edward Rigby, respecting the nerves of the uterus, at page 21 of his recent edition of Dr. Hunter's Anatomical Descrip-

tion of the Gravid Uterus. "Indeed," Dr. Lee," he says, "appears to express a conscious doubt as to the nervous structure of these masses, for he does not describe them as *continuous* or identical, but as merely *coalescing* with the branches of the hypogastric or spermatic nerves." I trust your readers will do me the justice to compare this paragraph with the following extract from my lecture on the nerves of the uterus, published in the *MEDICAL GAZETTE*, on the 30th December, 1842, (Vol. xxxi. p. 469). "From the form, colour, general appearance, and vascularity of these plexuses on the body of the uterus, and the resemblance they bear to ganglionic plexuses of nerves, and from their branches actually *anastomosing* and coalescing with the spermatic, hypogastric, and sacral nerves, I was led to conclude, on first discovering them, that they were nervous ganglionic plexuses, and constituted the special nervous system of the uterus enlarged by pregnancy. This dissection was examined by many of the most eminent anatomists in London, and they all admitted that the great plexuses on the body of the uterus were *continuous* with the spermatic, hypogastric, and spinal nerves. In a paper read to the Royal Society (Dec. 12th, 1838), I described the appearances displayed in these dissections and drawings. It was referred by the Committee of Physiology to Professor Owen and Mr. Kiernan, and these distinguished anatomists decided, from an examination with the microscope of small portions of the plexuses under the peritoneum, which had long been immersed in rectified spirit, that they were bands of elastic tissue, and not plexuses of nerves. The evidence furnished by the actual *continuity* of the plexuses with the great sympathetic was considered of no weight compared with the microscopic appearances. The microscope was the only test."

It is scarcely necessary to state, that this decision with the microscope was reversed by the Council of the Royal Society, and is now universally admitted to have been erroneous. Mr. Owen now acknowledges, in the most unreserved manner, that the microscope is not a test.—I remain, sir,

Your obedient servant,

ROBERT LEE.

4, Saville Row, Jan. 4, 1844.

ESCAPE OF URINE AT THE UMBILICUS.

To the Editor of the Medical Gazette.

SIR,

THE irregular construction of parts or organs of the body which now and then present themselves, must invariably prove matter of interest to the physiological inquirer; and when the anomaly is extremely rare it becomes worthy of record, as adding another remarkable fact to the curiosities of medical experience. The narrative of the case which I proceed to communicate will occupy but a small space in your widely circulated journal. The obstetric reader cannot but regard it as a singular vagary in his especial province of nature's handiwork, whilst the comparative anatomist will trace in it the more ample development of a rudiment of organization, occurring, as it were by accident, to an individual of the human kind, but which, on the other hand, seems essential to the constitution of many animals whilst in utero.

A few weeks since, a poor woman named Curtis brought a female child to me for advice, aged 13 weeks. From the period of its birth the urine had escaped at the umbilicus, the urethra being at the same time perfect. The excretion passed through the natural channel, and probably simultaneously with its evacuation from the navel, as the flow of it from the latter situation was not continual, but occurred at intervals, as if it were regulated by the detrusive action of the bladder and muscles associated therewith. The general appearance of the umbilicus was larger and more open than usual, and in the centre of the cartilaginous nipple-like projection I found an orifice which admitted an ordinary-sized probe. This was easily passed in the direction of the linea alba towards the bladder. It was clear to me, from a consideration of all the circumstances, that the common ligamentous band which passes from the fundus of the bladder upwards to the umbilical cord, and known by the name of urachus, had assumed, and retained subsequently to birth, the form of a duct, and this duct opened into the bladder. In the calf, and other quadrupeds, a communication resembling that which I have described

always exists; but, to use a quotation from that distinguished anatomist, M. H. Cloquet, "in man, it (the urachus) never forms a canal excepting in cases where the urethra is wanting."

I think it more than probable that during the intra-uterine life of this child a conformation of parts existed strictly identical with the allantois of other animals, and performing the same function, obscure as that function is generally admitted to be.

Previously to my seeing the case, pressure in a variety of ways had been resorted to without benefit. I recommended the mother of the child to take it to the County Infirmary, in order that the opening might be closed either by suture or other surgical means. It was treated by a simple suture, dressed with a pledget of lint, and secured by adhesive plaster.

The case was no longer under my inspection, but I understand the escape of urine was completely arrested for a fortnight, when it again found vent at the umbilicus.

A more effective union might be accomplished by means, I should say, of a small incision, the edges of which might be kept in apposition by suture, or plaster conjoined with suitable pressure.—I remain, sir,

Your obedient servant,

T. H. STARR, M.D.

Kettering, Northamptonshire,
Jan. 6, 1844.

OPIUM IN HERNIA.

To the Editor of the Medical Gazette.

SIR,

THE following is a case showing the good effects of opium in strangulated hernia.

I was sent for, at 10 P.M. on the 24th inst. to visit R. H. aged 45, a stout, muscular man, suffering under strangulated scrotal hernia in the right side. He had been trying for an hour to reduce it, having done so frequently before, but now he informed me it was a great deal larger. He was vomiting, and complained on the least pressure. In consequence of the extreme tenderness I did not persevere in the taxis, but decided on putting him under the influence of opium. I gave him two grains every fifteen minutes, until he had taken six grains, and to use hot

fomentations. Shortly after the first pill the vomiting ceased; and when I visited him again at half-past 12 P.M. I found them preparing to come and stop my visit, as he had got relief. I found him, as he said, exceedingly comfortable; it was quite evident he was enjoying all the luxury of an opium eater. Upon inquiry, he told me he had not touched the swelling, but that it had gone away of its own accord.

I am, sir,

Your obedient servant,

J. M. WALKER, M.R.C.S.L.

Newcastle-on-Tyne, Jan. 1, 1844.

MEDICAL GAZETTE.

Friday, January 12, 1844.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medice tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

SOME LATE TRIALS AT THE WINTER ASSIZES.

SOME time has now elapsed since we last directed the attention of our readers to the practical lessons in forensic medicine afforded by the trials which take place in our courts of law; and we, therefore, comment the more readily on three cases of the kind which occurred during the course of the last month.

CASE I.—At the Liverpool Assizes, on the 22d of December, Ann Mc Cormick was indicted for murdering her infant, five weeks old, at Manchester, by administering arsenic to it. The case was, unfortunately, but too clear. The mother bought arsenic at a druggist's, and gave it to the child in its porridge. A woman, in whose care the infant was left, not knowing that the porridge was poisoned, gave it additional portions. This caused repeated vomiting; yet the next day the symptoms were so slight, that when the child was taken to the infirmary, nothing was prescribed for it.

The counsel for the prisoner does not

appear to have touched upon this point, though something might have been made of it. Perhaps the omission is merely in the report, which was probably drawn up by a non-medical hand. It is deeply to be regretted that these medical trials, so interesting and so important, should seldom or never be reported by men understanding the points on which they turn. In the present instance, several things in the evidence require correction or elucidation; but we do not always know whether to attribute them to the witnesses, or to the reporter. Thus Mr. Holland, house-apothecary to the infirmary at Manchester, is made to say, that in fatal cases of poisoning by arsenic, "the first symptoms are unusually violent, so far as pain and vomiting are concerned."

The context shews that Mr. Holland did not say "unusually," but "usually." The symptoms are usually violent; and their slowness, therefore, masked the case at the infant's first visit to the infirmary.

Mr. John Davis, a lecturer on chemistry, found arsenic in the porridge, the vomited matter, and intestines, but not in the stomach or duodenum. "The bottle containing the brain, liver, lungs, and heart, were [was] saturated with arsenic." Here again must be a slip of the reporter; for though we might expect to find traces of arsenic in the viscera, any thing like saturation of the bottle would throw suspicion upon the case.

Mr. Davis says that he found arsenic by both the usual tests. It is not stated what these tests are;—perhaps the ammoniacal nitrate of silver, and the ammoniacal sulphate of copper; but the detection of arsenic in organic fluids by these re-agents would have required preliminary steps, of which no mention is made by the reporter. Was Marsh's test used?

We will not comment any farther upon this trial, which presents no remarkable features to the medical jurist, except to observe that the counsel for the prisoner was evidently acquainted with Orfila's discovery of the normal presence of arsenic in the human frame.

We are not quite sure that this discovery has been absolutely and unanimously accepted as a fact by medical jurists; but even if indisputably proved, it is not likely to cause much embarrassment in toxicological investigations; for the arsenic which is innate in human tissues gives the very faintest indications of its presence, while that which is criminally administered is commonly abundant.

We must not omit to mention, that the child lingered twelve days before it died. Ann M'Cormick was convicted, and sentenced to death.

CASE II.—A general practitioner, and one Tomlinson, whose rank is not mentioned, were tried at Derby on the 22d of December, for administering medicine to Sarah Hand for the purpose of procuring abortion. In one count it was stated to be *savine*, in another "a certain noxious drug to the jurors unknown."

Mr. Willmore addressed the jury for the prosecution at considerable length; but as his speech has not been reported, we are left to conjecture the motive which could have urged the surgeon to the commission of such a crime. As for the man Tomlinson, Sarah Hand was with child by him.

No satisfactory proof was given or offered that *savine* or, indeed, that any injurious drug had been administered. The woman, Sarah Hand, who had already had a child by Tomlinson, appeared to have been actuated by jealousy at his conduct with another woman, and by anger at his not marrying herself. Besides her *liaison* with

Tomlinson, other frailties were laid to her charge, which seem to have thrown additional discredit on her testimony.

Tomlinson asked the surgeon for some medicine for his sister, and received a mixture of aloes, jalap, Epsom salts, and water. Hand took this, or, if her evidence was correct, something stronger, as the symptoms were so violent that her life was in danger. Abortion did not take place.

The evidence of the woman, however, not being believed, the case fell to the ground. The acquittal of the surgeon was most triumphant. The jury, without troubling the learned counsel to call witnesses for the defence, turned round for a minute, and brought in their verdict of acquittal. This was followed by loud and successive plaudits in the court. Tomlinson, too, was acquitted, but not quite so exultingly. The jury deliberated for about ten minutes, and their verdict of "not guilty" was again followed by loud and repeated plaudits; but the foreman, at the same time, observed, "that they thought the prisoner had acted very wrongly, but did not feel satisfied that it was a noxious drug."

Almost the only toxicological point in this case is the effect of aloes in pregnancy. A medical witness observed that aloetic medicines were expressly prohibited in pregnancy, because of their injurious action upon the uterus at that time; but he added, that in his opinion, aloes taken in the quantity mentioned [it is not stated in the report] would not have done any injury, nor caused the symptoms of the case.

Denman, as our readers know, does not partake the general professional dread of aloes, remarking that "they are in common use among the lower class of people, because they are cheap, and conveniently given in the form of pills."

CASE III.—At the same place, and on the same day, John Winfield Grocock, aged 17 years, was indicted for violating the person of Eliza Ann Allwood, a child aged 11, and also for attempting to murder her.

The outline of the case may be given in a few sentences. The prisoner having decoyed the girl away, under pretence of giving her employment in a Derby silk mill, violated her person, struck her repeatedly on the head with a hammer, and left her for dead. He then gave himself up to justice as a murderer, asked for pen, ink, and paper, and wrote a minute account of the whole affair, with the exception of the rape, which he naturally supposed would diminish his claims to public sympathy, without adding to his pretensions as a monomaniac. His account concludes by saying, “as regards my intention for committing such an act, I was determined to be transported or hung, having at that time no means of obtaining a livelihood, but I cannot properly explain the motive for committing such an action.”

The prisoner described to the superintendent of police the spot where the crime had been committed. It was under a tree facing the windows of the mill at Borrowash. The grass was much trampled down; there was a quantity of blood upon it; and the handle and head of a hammer were picked up separately, for Grocock had struck this poor child till the instrument came in two. When taken to the Infirmary, one large and six smaller contused and jagged wounds were found upon her head. She recovered, however, and was one of the witnesses on the trial.

Grocock had possibly speculated on the favour shown of late to monomania, whether real or pretended, and had anticipated sporting in the same play-ground with Oxford and Macnaughten. In prison

he acted his part as well as he could. “He was calm and quiet,” says Mr. Douglas Fox, the surgeon of the jail, “when he did not know that he was watched, but rolled his eyes strangely when he knew that he was observed.”

Several witnesses were called for the defence. One proved that his general conversation was very strange,—that he talked very wildly; another that he said, “Mrs. Gee, I feel very curious—my head is very hot—I feel as if I should go beside myself.” Another, who was an out-patient at the Nottingham Infirmary, saw him there, and was alarmed at the wildness of his conversation and appearance. Lastly, his father proved that the prisoner’s uncle had been insane for 18 years, and had been in confinement; and that the prisoner, when 18 months old, had a fall upon a mop-nail, which cut his forehead severely over the eye, and left a scar which is still visible. In short, there was evidence enough to have got the prisoner off had it been backed by any of the medical witnesses. This did not happen; and Grocock was left to answer for his complicated crimes. The jury took a merciful view of the case, and found him guilty of the fourth count only, which charged the intent to do grievous bodily harm.

The sentence of the Court was, that he should be transported for life.

The jury expressed themselves not satisfied with the evidence of his insanity; but even if they had been, their verdict ought still to have been the same, according to Lord Brougham’s test, which we adopted in a former article: for it is evident from the paper which the prisoner drew up, and in which he professes that he committed the crime in order to be transported or hung, that he knew that he was about to do what was legally wrong; and this was quite sufficient to make him legally responsible. It might be added

that his wish to be *transported* or hung is a strong and unfavourable commentary on the laxity which of late has so often substituted Australia for the gibbet in cases of wilful and deliberate murder.

We will conclude by observing that the late refinement touching monomania is the most alarming improvement ever made in psychology. "Had I been hanged," said Oxford, in Bethlem, "there would have been no more attempts upon the Queen's life:" had Macnaughten been hanged, Grocock might have spared his bold attempt to be hung "or transported."

NEW CHARTER OF THE COLLEGE OF SURGEONS.

[We have in recent numbers offered our remarks very freely on the above. Our respected contemporary of the "British and Foreign" has taken a view somewhat different, which may be interesting to our readers.]

The first and most important remark that suggests itself in reference to this charter, is, that its whole purport is to regulate the College as a simple corporate body, and that it does not confer on it one atom of power or a single privilege in relation to the profession. The new College, like the old, can give no license to practise, possesses no control whatever over any class of practitioners, and can oblige no one to enter its ranks either as a Member or Fellow. All its privileges consist in its power to bestow a title on those who choose to seek it, according to certain regulations. The organization and government of the medical profession, therefore, are not at all interfered with by the provisions of the charter, and await the enactment of the Medical Bill, so long in preparation by Sir James Graham. It is, no doubt, unfortunate that the granting of this charter was not deferred until after the passing of the bill; as the provisions of the charter—which can only be regarded as a mere subordinate matter of detail—may be found to hamper the more important provisions of the general measure. The difficulty will be increased if the physicians' charter is also granted pre-

viously to the enactment of the Medical Bill. We hope, however, that although it will be more difficult to frame a liberal general law in perfect harmony with these charters than it would have been to frame charters in harmony with it, yet that the difficulty is not insuperable. Should this, indeed, prove to be the case, we doubt not that the author of the bill will not hesitate to get both charters modified, rather than endanger the soundness of a measure on which the future welfare and prosperity of the whole medical profession will probably depend. Our object, however, at present being merely to offer a few comments on the new charter, as a code of laws for regulating one of the most important corporate societies in the profession, we shall leave all consideration of the general subject until another occasion.

It will not, we presume, be doubted by any calm and impartial judge, that this charter is a great improvement on the old. Some of its provisions certainly might have been improved; but, looking at it as it stands, we think the profession owes a debt of gratitude to Sir James Graham for insisting (as we believe he did) on its more liberal clauses; while it is, in many respects, creditable to the judgment of those Members of the College who were mainly instrumental in obtaining its enactment.

No man of experience need be told that it could be no easy task to bring a body of men, however honourable, in the actual possession of exclusive rights of long standing, of power and of property, and responsible to no one, to forego, in a great measure, their dearest privileges. And it were well that, when we criticise the proceedings of such persons, we should reflect what might have been our own feelings, views, and conduct, in similar circumstances. Examining the charter in this spirit, we must regard its provisions, on the whole, as good; and we think we may confidently expect from those who framed it, yet further improvements in its more liberal parts, if it should be found, in the working, to be injuriously restrictive of the legitimate rights and free action of the new constituency.

By the new charter the system of monopoly and self-election is for ever abolished; and it remains entirely with the future Members of the College whe-

ther the Council shall henceforth be such as they deem fit to represent and rule them. As by the new provisions, every Member may claim to be admitted a Fellow on attaining the age of 25; and as the election of the Council is left entirely in the hands of the Fellows, no apprehension need be entertained that the appointment of Councillors will be brought about by unfair means, or, consequently, that improper persons will be elected. The examination for the Fellowship will, of course, be of such a nature as any well-informed surgeon can pass—no Council would dare to make it unnecessarily severe: it cannot, therefore, be doubted but that the great majority of future Members will become Fellows, and thus a body of electors will always exist too large to be corrupted or seduced or “managed” in any way. Most important advantages will result from making the admission to the Fellowship through the door of a higher examination, and at a period subsequent to the ordinary termination of school studies. The men desirous of this honour—and, as we have said, we believe most Members will be so—will take care that in the first instance they *study up to the mark* of the Fellowship; and that should they at first take the inferior degree of Member, they will *keep up* the knowledge then obtained, or even continue to improve it, until they reach the age for claiming the higher title. Had we been framing the charter, we should have made the examination for the Membership a strict one, and the only one, leaving admission to the Fellowship contingent on the attainment of a certain standing as Member—say seven or ten years—and the payment of a moderate fee. We, however, do not quarrel much with the present arrangement, and see in it some advantages over the other, the most important of which is that just stated. A more serious objection to the new charter, in the eyes of many, will probably be the exclusion from the Council of practitioners of pharmacy and midwifery. In some respects we consider this as an important defect, more especially as regards the practitioners of midwifery. Although well aware that the progress of reform is not yet sufficiently advanced to justify any measure that would virtually forbid surgeons to practise pharmacy (that is,

to send out their own medicines), we are still glad to see any enactment that tends to abolish this most impolitic, and, we may say, degrading association of trade with science. And we entertain no doubt whatever that the clause excluding practitioners in pharmacy from the Council of the College, will eventually have a powerful influence in abating this crying evil. Unfortunately, however, the coupling of midwifery with pharmacy as joint causes of exclusion, will interfere most materially with the progress of this reform. General practitioners may, without difficulty, cease to supply their patients with drugs; but we cannot see how they can cease to attend cases of midwifery without such a sacrifice of their interests as must more than counterbalance even the honours and advantage of a seat in the Council. In our zeal for the abolition of the trade in physic, we would have almost consented to the exclusion of practitioners of pharmacy even from the Fellowship, provided this obnoxious and impolitic exclusion of practitioners in midwifery from the Council had been abandoned. After all, however, this can only be regarded as a minor evil; and sinks into insignificance when viewed in conjunction with the real and substantial advantages conferred by the charter. We cannot doubt but that there will always be found in London and its vicinity enough of men in the class of pure surgeons (including many who have ceased to practise pharmacy and midwifery) from among whom the Fellows—that is, *the general practitioners* (for the vast majority of Fellows will eventually be general practitioners)—may choose fitting representatives and officers. It even will lie with themselves, hereafter, to obtain such modifications in the charter as they may deem more to their own honour and advantage. Every general practitioner may become a Fellow if he please; and every Fellow may, even by the present charter, render himself eligible for the Council: and it will go hard, if, with such potential vantage-ground, the majority should not be able to obtain the virtual, if not the ostensible supremacy in the direction of their own affairs.

The prescribed mode of electing members of the Council seems to us, also, if not a positive defect, certainly of doubtful propriety. It, no doubt,

obtained admission into the new character because it formed a prominent feature in the old,—of which, indeed, it is an improvement. The obvious and natural mode of proceeding, as it appears to us, would have been—to limit the eligibility to be members of Council, to Fellows of a certain standing—say ten years—and then leave the selection to be made from this class, without any restriction as to individual seniority. And we cannot but apprehend that the reasonable desire on the part of the Fellows, to choose the men they may deem best qualified for the office of Councillors, may, in the working of this part of the measure, lead to results seriously affecting the harmony and respectability of the institution. We doubt not, however, that the more liberal members of the Council will take care, by great reserve in proposing the immediate re-election of retiring members, not to compromise the rights or just expectations of those placed lower on the list. In this manner we think the clause in question may, in a great measure, be deprived of the danger of which it appears to us to be at least a possible source. With regard to this clause, however, as well as to others which may seem objectionable, we doubt not that the new Fellows will have sufficient judgment and discretion not to condemn it or them absolutely, until their value has been proved in actual practice, and on more than one occasion; as it will be much more for their interests to put up with inconveniences or evils for a few years, and then to have them permanently remedied, than to run the risk, by a hasty decision, of only exchanging one blemish for another. There was never yet a code of laws devised for the government of any institution, which did not call for and receive subsequent alteration and improvement; and we have no right to expect that the new code of the College of Surgeons should differ in this respect from all its predecessors.

ROYAL COLLEGE OF PHYSICIANS.

To the Editor of the Medical Gazette.

SIR,

A CORRESPONDENT who subscribes himself "A Licentiate" (of the College of Physicians,) in the MEDICAL GAZETTE

of last week (Dec. 29,) appears in great distress, poor soul! at the idea of being contaminated by the Extra-Licentiate of the same Collège. It makes one's tender heart ache with compassion for his misery at the prospect of such an alliance. "To them," (the London Licentiate) he cries, "it would be an injustice to thrust upon them a body of men who had not possessed the same qualifications."

To be sure it would! Let your touch-me-not correspondent ask Dr. Francis Hawkins, the Registrar of the College, what the difference consists in between the qualifications of the two classes of Licentiate: he will find, in all probability, that they are the same for both classes; a fact that he ought to have known before he presumed to meddle with such a subject.

As to the "examination," Sir Henry Halford, the President, who is present at, and superintends, the examinations of the members, of all classes, says, before the Committee of the House of Commons, that the examination of the London and the country Licentiate "is the same: it is the same examination." I should be disposed to take the President's word quite as readily as I would that of your *liberal* correspondent.

As some of your readers may not have taken the trouble to inform themselves upon this point, I will explain to them how the case stands.

The Act of 14 and 15 Hen. VIII., consists of the Charter (granted four years previously,) and of additional clauses. The charter applies only to the city of London and seven miles round. Another clause of the Act applies to the whole of England, beyond seven miles of London. According to the Charter, the London Licentiate is examined by the President and four censors, and no one can practise therein without possessing letters testimonial signed by the President and censors. According to the clause relating to the rest of England, candidates must be examined by the President and elects, and no one can practise beyond seven miles of the city, who does not possess letters testimonial signed by the President and elects. The consequence is, that the London Licentiate has no right, according to law, to practise beyond seven miles of the city of London; nor have the country Licentiate

any right to practise within seven miles of the same. This state of things might have answered very well 320 years ago, but, in this railway age, I believe the College see the inconsistency of it, and want to do away with it.

It is probable that the difference in the form of the examination of candidates arose from those of London and those of the west of England being examined by two distinct boards. The censors adopted the mode of dividing the examination into three parts, viz. 1. In parte anatomica; 2, in parte physiologica; and 3, in parte pathologica; whereas the elects adopted the plan of going through the whole of the examination, in all those branches, at one sitting. This plan, evidently, was had recourse to for the convenience of candidates who had a long distance to go to London; which, in those slow-travelling and throat-cutting times, was a subject of some consideration. I have perused several of the examination papers of the intra-Urban Licentiates, and I find that they, in each of the three departments, contain eight or nine questions, much the same as those put, *viva voce*, at the examination for the extra-Urban license. They are good, fair, practical questions, for the most part in both cases. The Latin works used in both are the same.

Now, surely, I cannot see why the elects should not be as good examiners as the censors; meaning not the slightest disparagement to the latter. We have heard something about age making a difference. We have Admirals commanding fleets and battering down forts at 80. We have Generals of districts nearly as old. We have a Lord Chancellor of 74; and some other judges running fast on. We have the Duke of 74, directing the whole of the army of the empire. Is there any thing in particular connected with our profession calculated to cause premature imbecility? or are the members of our profession more illiberal than those of any other, that they should insinuate such a thing against persons well known to possess full vigour of mind, and to whom the public do not hesitate to entrust their care of their health and lives?

Your correspondent adds, in his very liberal style, "to be consistent, the College must either raise the present Licentiates to the rank of Fellows, or

allow the extra-Urbans to remain, as they are at present, a distinct grade."

That's the way the Devil reasons: "if I cannot get to heaven myself, I will take care that you sha'n't." That is an incontrovertible argument.

Let me conclude, sir, by observing, without the least intention, or wish, to detract from the merits of the London Licentiates as a class, that the extra Licentiates are for the most part men in extensive practice, and of many years' experience, fixed in the different boroughs and towns of England, and who have kept up their classical, as well as their anatomical knowledge, whilst pursuing the practical part of their profession. The cause of their late increase is to be found in the regulations of the College, issued in 1838, under which men of liberal education, wheresoever acquired, are admitted as candidates for its diploma. Before that period the country physicians were mere Scotch graduates, who obtained their diplomas, as boys comparatively, at one and twenty years of age, and who were allowed to practise in England unmolested, although contrary to the Acts of Parliament, in that case made and provided, as your "Licentiate" will find, by referring to it. But the College wants reforming.

I am, sir,

Your obedient servant,

A RURAL PHYSICIAN.

January 4, 1844.

CASE OF RUPTURE OF THE UTERUS

IN A WOMAN WHO HAD TWICE UNDERGONE
THE CÆSAREAN OPERATION.

By WM. BOWEN, M.D., of Massillon, Ohio.

FEW of the many histories of unfortunate child-bearing are more painfully interesting to the medical reader than the following; and certainly none, with which we are familiar, presents features in obstetrical surgery more extraordinary; whether it be viewed in reference to the great constitutional stamina of the unfortunate patient, which enabled her to survive two successive operations, of the severity and danger of the Cæsarean section, or in regard to the circumstances which seemed to the practitioner who had charge of her case, to warrant a resort to such a hazardous procedure. The story of Mrs. S.'s lying-in-room adventures is one of such remarkable incident, and of such good and bad fortune, as to entitle it to a place among

those told of others, on whom the primitive curse, "In sorrow shalt thou bring forth children," has been most heavily visited.

Mrs. S., after having had four unfortunate labours, two of which (the third and fourth) were terminated by the abdominal section (her accoucheur, Dr. R. Estep, supposing she had deformed pelvis, which would render delivery of a living child at full time impossible), had the good fortune in her fifth confinement to give birth to healthy and vigorous twins at full time and of large size; but falling in labour the sixth time, she suffered laceration of the uterus, and survived but a few hours.

For the details of this last labour, I am indebted to my friend C. H. Preston, M.D., an intelligent practitioner of this county; for the history of the preceding one I am under obligations to Dr. Robertson, a skilful and popular physician of the adjoining county (Columbiana); while a circumstantial account of the third and fourth labours, in which the abdominal section was deemed necessary, and performed by Dr. R. Estep, has been published by the operator in the July number of the *Western Journal of the Medical and Physical Sciences* for 1836. As it may be fairly inferred that the disastrous termination of the last labour of Mrs. S. was owing mainly to the weakened condition of the uterus at the place where it had been twice incised; and as the circumstances under which such bold and dangerous surgery had been previously practised are given with some minuteness in the published report, the interest and value of the case, which it is more especially our object to communicate at this time, will be enhanced by presenting to the readers of this journal such portions of that report as seemed to the reporter to embody the best reasons for his practice; and whether these extracts be received as detailing a practice sanctioned by good sense and standard authorities, as conscientious surgery calculated to subserve the best interests of the patient, and worthy of imitation, or as a measure which in wanton violation of the plainest rules of obstetrical management unnecessarily jeopardized the life of the woman, they must still be regarded as parts of a document of no ordinary value.

In 1830, Dr. Estep informs us, he was called to attend Mrs. S., aged about 20 years, in her first labour: delivery was accomplished by the forceps. Suspecting deformity of the pelvis, he made an examination, and "found the antero-posterior diameter contracted to such a degree as to preclude the possibility of her ever giving birth to a living child approaching the ordinary size."

In 1832, he attended this woman again, and succeeded, with some difficulty, in delivering with the forceps of a "very small dead fœtus:" a more careful examination of

the pelvis was now made, and it was found that the sacro-pubic diameter at the superior strait was reduced below two inches.

In 1833, Dr. E. says, he was called a third time to attend Mrs. S. in labour: she informed him that she had been in labour several hours, and that during the third or fourth pain she distinctly felt something "give way." From this account, Dr. E. suspected rupture of the uterus; he immediately introduced his hand, and "thought" he discovered a rent in the anterior wall of that organ, near its middle. Turning the child, with a view of delivering by the feet, was determined upon (the presentation was one of the vertex). The feet were brought down, and the trunk delivered; but no efforts were sufficient to induce the head to pass. "After three hours' indefatigable exertion (he says), I was unable to get the head engaged in the superior strait. Relinquishing all hope of success by this artifice, and being thoroughly assured of the child's death, I now separated the head from the trunk, in the vague hope of being able to get a better diameter of the head, or by locking the finger into the chin, to be able to apply a more efficient force; but in this I was likewise unsuccessful." After fruitless endeavours to extract the head with a perforator, Dr. E. proposed and performed the section of the abdomen: he found a slight rent in the uterus, which he enlarged to the extent of five or six inches, and extracted the head through it. The placenta was delivered by the natural passages; the wound in the abdomen was closed in the usual manner, and the woman recovered in a short time.

In 1835, Mrs. S. was again in labour, and Dr. Estep was called in consultation with Dr. Tolerton. This call, Dr. Estep says, he was prepared for, by having "every instrument and agent which could possibly be called for in requisition, carefully packed up where I could lay my hands on them at any moment." On reaching the residence of the patient, and examining per vaginam, he found "an arm presentation and a dead child:" the evidences of the child's death are not given. The Cæsarean operation was again resorted to, without attempting delivery by any other method. This operation was as successful as the other; a dead child was extracted through the opening, and the woman soon recovered.

In 1838, Dr. Robertson was called to see Mrs. S., who was again in labour. On reaching the house, he says, "I found she had given birth to healthy and vigorous twins; their large size, and the globular form of their heads, left me no room to doubt the mother's having a tolerably ample pelvis. I removed the placenta, and satisfied myself that the pelvis was not as faulty as had been charged. Making a pelvimeter of my hand,

which I introduced for that purpose, I placed the ulnar edge of it upon the sacral projection, while its radial aspect scarcely touched the ossa pubis; thus giving the sacro-pubic diameter a space of about three and a half inches.

In 1841, my friend Dr. Preston wrote to me as follows:—"Last week I was called to see Mrs. S., in consultation with Drs. Robertson and Carey. I learned that the labour had begun about eighteen hours previously; that a midwife had been called in, who found a vertex presentation, and gave promise that labour would soon terminate. The uterus had been acting with great energy, when suddenly the woman exclaimed, "something has given way." Considerable hæmorrhage ensued, with vomiting and syncope: the uterine contractions ceased. In this condition Drs. Robertson and Carey found her, and matters had not improved any when I arrived. Examining per vaginam, coagula of blood were found, but the child's head was not within reach of the finger. These evidences, with those furnished by an external examination of the abdomen, made it plain that the uterus had ruptured, and that the child had escaped wholly or in part into the abdominal cavity. I proposed attempting delivery by introducing the hand and searching for the feet, with a view of bringing the child back through the rent in the uterus, and delivering it footling through the natural passages; but my colleagues, without doubting in the least the practicability of this method, were disposed to regard the woman as moribund, and to prefer that mode of delivery which would least endanger the life of the child, if, perchance, it still survived; they, therefore, insisted on resorting to the abdominal section. Observing that a division of the abdominal integuments through the old cicatrix would be unattended with pain or hæmorrhage, owing to its imperfect union and organization, I acquiesced in the propriety of the measure, and I am certain that no mode of delivery would have saved the woman. Dr. Robertson performed the operation. We found the child dead, and almost entirely in the abdominal cavity, the uterus having given way through the whole extent of the former cuttings. After the child and secundines were delivered, the woman seemed to revive; but her last labour had come: she survived about thirty-six hours." Before leaving the patient, Dr. Carey took special pains to ascertain the true dimensions of Mrs. S.'s pelvis; he avers that the transverse and conjugate diameters are of good size, but that the depth of it posteriorly is less than usual.

It will be perceived that the parties who paid obstetrical attentions to Mrs. S. have joined issue in regard to the size of her pelvis. Dr. Estep assures us that the contrac-

tion was such as "to preclude the possibility of her ever giving birth to a living child, approaching the ordinary size;" "that the sacro-pubic diameter was below two inches;" and of course it was upon this view of the condition of the pelvis that the propriety of turning and decapitation of the child, and the subsequent section of the abdomen, to deliver the trunkless head in the third labour, and the immediate resort to the Cæsarean operation upon finding "an arm presentation and a dead child" in the fourth confinement, are predicated. Drs. Robertson and Carey declare the pelvis to be of tolerably "good size;" that the sacro-pubic diameter, at the superior strait, measures at least three and a half inches. Without attempting to determine the truth of the matter at issue, by the number and credibility of the witnesses on each side, we think the circumstance of the birth of the twins, and the facility with which Dr. Estep turned and delivered the trunk and extremities of the child he beheaded, establishes the truth of Drs. Robertson and Carey's declaration in regard to the matter, as clearly as if the pelvimeter of Contouly, or the callipers of Baudelocque, had been applied, and had testified to a reasonable amplitude of pelvis.

Admitting Dr. E., however, to be correct in his estimate of the size of this woman's pelvis, was it not a strange practice which sought to pull a child, footling, through a pelvis contracted in its sacro-pubic diameter at the superior strait to "below two inches?" He is an industrious accoucheur who devotes his muscles to "three hours' indefatigable exertion" to bring the large diameter of a fetal head (occipito-mental, five inches) through an opening of less than two; and to have failed to accomplish so extraordinary a feat is no proof of the want of respectable physical qualifications. Separating the head from the trunk, "in the vague hope of being able to get a better diameter of it, or by locking the finger into the chin, to apply a more efficient force," was a device possessing strong claims to originality, but one which has not yet found favour in the eyes of our best obstetrical authorities. Dr. Dewees (page 580, *System of Midwifery*), says, "For what reprehension, indeed I had almost said punishment, would be sufficiently severe for that practitioner who, after having destroyed the child, should find it impossible to deliver it; and then, for its accomplishment, subject the poor woman to the Cæsarean section?" If it is difficult to recognize the necessity for so perilous an operation as the Cæsarean, in the third labour of Mrs. S., it is by no means an easy matter to discover good reasons for resorting to it again in her fourth confinement. It would, however, be paying a poor tribute to the discernment of

the reader to suppose him blind to the fact, that, in conducting the third and fourth labours of Mrs. S., rules were set at naught which have been held sacred to common sense by every writer on midwifery.—*American Journal of Medical Sciences.*

AMMONIA GROTTTO.

DR. CONSTANTIN JAMES, who, while travelling with M. Magendie, made some observations on the Grotto del Cane, noticed in the *MEDICAL GAZETTE* for Nov. 17, p. 222, has made some more remarks on a neighbouring phenomenon in the *Gazette Medicale* of the 9th instant, of which we give the substance. In the same number is a notice of Mr. Smee's opinions, on the inhalation of ammonia as a therapeutic agent.

At a little distance from the Grotto del Cane, and at the foot of a rising ground remarkable for its rich vegetation, is the *Grotte d'Ammoniaque*—ammonia grotto. It was discovered accidentally about a dozen years ago. The Prince of Capua had a tent pitched, for the convenience of shooting wild fowl, near the Lake of Agnano. Some workmen in the surrounding plantations, while digging a ditch, felt suffocated by the gaseous emanation from the soil. It was supposed to be like that of the neighbouring Grotto del Cane; and, in fact, animals placed in the opening speedily died of asphyxia. The gas, however, when analysed, proved to be not carbonic acid, but ammonia, and gives its name to the grotto erected on the site of the ditch. Much less celebrated than its more popular neighbour, this grotto is not less interesting and attractive to the curious; and it possesses, moreover, valuable remedial powers.

The interior of the grotto appears like a ditch, nearly square, about a metre in depth, covered by masonry to the height of three metres. It is entered by a small door, for opening which rather a high fee is exacted. On entering, no smell or other indication of the presence of ammonia is perceived while standing upright. The soil is dry, brownish, friable, without a trace of vegetation. The gas is found at the lower part of the grotto, contrary to what would be expected from its low specific gravity. This depends, doubtless, on some physical or chemical combination not yet accurately determined, and requiring more exact observation. It may be presumed that the gas is in the state of a carbonate, though the usual name of ammonia is retained in this description.

The essential characters of an ammoniacal exhalation are easily detected with the ordinary re-agents. Reddened litmus paper is turned blue; hydrochloric acid in an un-

stopped bottle gives the white vapour of hydrochlorate of ammonia. The peculiar penetrating odour, the disagreeable sensations, and the pungent flavour of ammonia, were perceived on raising the gas with the hand to the mouth and nose. A torch was extinguished in it, and the height of the stratum was thereby measured. It entirely filled the ditch. It was ascertained that no escape took place at the threshold or elsewhere. When made to flow out, the ditch filled as fast as the gas was wafted out, so that the same level was preserved. The secretion was then arrested, as if the air saturated with ammonia could take up no more.

The head may safely be plunged into the gas, if care be taken not to breathe it, which would risk suffocation. Asphyxia from privies is owing in great degree to the ammonia they disengage. It is well, too, to stop the mouth and nostrils, to prevent disagreeable irritation and sneezing.

While examining the spot M. James met with an invalid, an Englishman, with whom he speedily made acquaintance, and whose case shewed him some of the remedial powers of the grotto. For more than a year this patient had suffered from chronic engorgement of the eyelids, injection of the conjunctiva, and weakness of sight, which no treatment had relieved. Having quitted the fogs of England, he had travelled to Naples, and hearing, in an excursion to the grotto, that many persons suffering as he did had been cured by fumigation with its gas, he tried it, and in a few days got well. It was certain that the conjunctiva had nearly regained its whiteness, only a few varicose and mobile vessels remaining on the outer side of the right eye; the left was still better, and the sight of both had become stronger. The pupils, though rather dilated, contracted naturally.

This was his fourteenth fumigation, and was conducted as follows:—Closing his nose and mouth, he stooped with his face in the gas for seven or eight seconds at a time. His eyes soon filled with tears, which at length poured down in torrents, the eyelids winking rapidly. After several immersions he washed his eyes with very cold water, and put on blue goggles furnished with black taffetas. For half an hour the eyes remained red, and the pupils strongly contracted, with some pricking and shooting pain. By degrees nothing remained but lachrymation, which generally lasted all day.

This fumigation acts no doubt like other applications, which stimulate the languid vitality of the tissues. It may perhaps be better than some others, as exciting the small vessels without leaving behind a foreign substance. The *custode* said he had seen many amanrotic patients treated thus; and told the case of a man quite blind, who, by

fumigation alone, had recovered his sight*. Mr. James is not surprised at this, as Scarpa has employed with advantage the vapour of ammonia in treating certain paralyses of the iris and retina; but asks whether the gas of this grotto may not be more efficacious than the usual compounds of ammonia, as natural mineral waters are far better than artificial?

Mr. James thought it needless to repeat on himself the experiments he had seen tried on the Englishman; the custode had no scientific habits, had not even a dog, for visitors are so few that the demand for suffocation would not pay for its keep. *Heureusement* Mr. James had brought some rabbits. One of these put into the grotto ran about distractedly for escape, fell down, scratched its nose violently, tried to rise, fell again, and uttering the well-known cry which indicates speedy death—the eyes burning, the mouth half open, the body trembling and convulsed—died in about a minute. All the means of resuscitation which had succeeded at the Grotto del Cane failed against this more terrible suffocation. The one gas, merely, does not support respiration; the other is actively deleterious. There is a similar difference between nitrogen and carbonic acid, and different gases vary in activity and power. Sulphuretted hydrogen is worse than ammonia. The dead rabbit was examined, but the death had been too rapid for the ordinary changes of asphyxia to take place. A quarter of an hour afterwards the lungs examined again showed all the signs of pneumonia by extravasation. In asphyxia, then, the more rapid the death, the slighter the changes of structure. The cornea was dull; the eyes and nostrils clogged with viscous secretion. These effects of its caustic properties may sometimes in medico legal cases determine that ammonia has been the cause of suffocation. From motives of humanity only one other rabbit was sacrificed to an experiment which could gain no value by repetition; but a frog was put in, and after surprising the experimenter by the preternatural vigour of his leaps, died in one minute. The surface, not of the lungs, but of the skin, was thus painfully suffocated, being mucous, permeable, and unprotected. A few remarks on this subject, in connection with the known properties of the permeable tissues, may be reserved for a future occasion.—*Gazette Médicale*.

VEILBACH.

As to Veilbach, it is quite a new creation, of which no account is any where to be found. Its situation is in a W. S. W. direction, and about an hour and three quarters from Wiesbaden, ascending by the road leading to Frankfort. The spring is in the centre of a rotunda or temple, and flows incessantly and profusely through four marble spouts, around a pillar or shaft placed in the centre of a marble basin, into which the water flows; while deposits are formed, in the course of the day, both in the spouts and around the brim of the basin, which are cleared away by the morning. These deposits are sulphur, the characteristic gas of the water being sulphuretted hydrogen, of which Kastner, the professor of chemistry, who analyzed the water in 1839, found nearly three cubic inches (2.949) in a pint. In a glass, the water appears perfectly colourless and transparent, a few very minute bubbles of gas being seen ascending for a short time. Tasted deliberately, one recognises at once that peculiar sweetish flavour belonging to the sulphuretted waters, which proceeds from the decomposition of vegetables, or from peat-earth, and not from pyrites or shale, as first pointed out by me. It has no decided saline taste during or after drinking it; but a species of pricking of the tongue, as when a green mustard-plant is chewed, manifests itself, and continues for some time. This sensation is never present in rock, or really mineral, sulphuretted water. Judging by the quantity of alkaline carbonates said by Kastner to be contained in this water, amounting to more than the half of the whole solid ingredients in it, a medical man would consider it not only as a peculiar, but as a most valuable addition to that class of mineral waters of which Harrowgate may be taken as the type. In its effects, however, I should expect it to differ materially from the latter water, in which neither the carbonate of soda and potash, nor the carbonate and muriate of magnesia, is present, as in the very singular water of Veilbach. A longer experience is wanting to tell us what its specific virtues are likely to prove.

A large insulated hotel has been erected near the spring, having a well-arranged establishment for baths; and in this, the only building in the place, the sixty or eighty invalids who come to drink the water are lodged and boarded. Veilbach is an important addition to the long list of mineral sources of the duchy of Nassau, from its being the only sulphur water discovered there.—*The Spas of Germany Revisited*. By Dr. Granville.

* Readers of the *Times* would probably prefer, what readers of the *Gazette* would doubtless recommend, viz. that amaurotic patients should spend their guineas in trying the effects of the grotto and green spectacles, rather than in undergoing, first, fumigations, and afterwards litigation for fees, with a certain London practitioner.

EXCISION OF THE WHOLE LOWER JAW.

THE case of excision of the whole lower jaw, related by Dr Bartolome Signoroni, is interesting as showing that patients may recover after removal of the whole jaw, and preserve the power of swallowing, and the faculty of speech. In this case, on account of an osteo-sarcomatous affection, the whole jaw was removed at its articulations. The patient speedily recovered, and was a few months afterwards exhibited at Padua, to the Italian Scientific Association. He had completely regained his health, swallowed easily, and his speech was scarcely defective. It is much to be regretted that the details of this case are not given; it may, however, be gathered from the remarks which follow the simple announcement of its success, that the bone was extracted piece-meal, being divided into portions by means of the cutting pliers introduced through subcutaneous incisions. It is to this mode of operating the author attributes the small quantity of blood lost, the rapidity of the healing process, and the general success of the operation. No mention, however, is made of the size of the tumour, the amount of the lower jaw which it involved, or the necessity which existed for removing the whole bone.—*Annali Universali*; and *Edin. Med. and Surg. Journ.*

ON THE DESTRUCTION OF THE CONTAGION OF THE PLAGUE.

A COMMITTEE of Russian medical authorities has been making experiments in Egypt, on the destruction of the contagion of the plague, by means of hot air. The woollen articles of clothing were worn by persons decidedly affected with the disease, for twenty-four hours, exposed to a heat of 144° to 167° Fahr., in a heated room, and were then worn by persons in perfect health, who had held quarantine in disinfected clothing. These persons, fifty-six in number, wore the woollen clothing during a fortnight, and not one of them became subject to the plague for several weeks after the experiment.—*Pharmaceutische Central Blatt*. No. 48, Oct. 1842.

CURIOUS CONFERVOID ANIMAL, OBSERVED BY DR. VAN OYE.

THIS conferva was found in the stream of a shallow brook, and being examined with a magnifying glass, and a microscope, presented the curious spectacle of a double transformation. The tubes of the conferva separated in the water into a considerable number of animalcule possessed of life and voluntary motion; and they afterwards

united again at the expense of these same animalcule, in which all animal life had become extinct.—*Annales de la Société Médico-Chirurgicale de Bruges*.

MANCHESTER UNION HOSPITAL.

THE Senate of the University of London has recently recognized Certificates of Attendance on the Medical Practice and Clinical Lectures of the Manchester Union Hospital.

NOTICES TO CORRESPONDENTS.

We beg to refer Dr. Ritchie to our number for Dec. 22, 1843.

It would be contrary to usage to copy the critique alluded to by Mr. G., of Liverpool.

Mr. Higgins' answer to Dr. Badeley next week; unfortunately it was too late for the present number.

Papers have been received from Dr. Percy, Dr. Knox, Dr. Burton, Dr. J. B. Thompson, and Dr. Heaton.

ON PNEUMO-THORAX :

AN ESSAY,

*Read (in part) at the Physical Society of
Guy's Hospital,*

By H. M. HUGHES, M.D.

One of the Assistant Physicians to the Hospital.

[Continued from p. 471.]

CASE VII.—*Pleuritis—Pneumonia—Gangrene of the lung—Pneumo-thorax—Gas in the pericardium.*

J. B., aged 30, an Irish labourer, with dark hair and nearly bald head, looking as old as 45, was admitted into the hospital under my care, August 18th, 1843. He stated that he was quite well a fortnight before, and that he had not been previously troubled with cough, and had never suffered from hæmoptysis; but that twelve days ago, while hard at work, and perspiring freely from his exertion and fatigue, he was suddenly seized with such a severe pain in his left side "that he could not stir;" that he had had no cough, but had suffered only from pain in the side, and that he had neither had, nor sought for any medical advice, till he presented himself among the out-patients at the hospital. He was far too ill to send away, and therefore, though in a wretchedly filthy state, after being well washed with soap and warm water, he was put into a warm and clean bed; and depressed as the poor fellow was, he appeared exceedingly happy and grateful for his accommodation. He was indeed already very low, his face pale, his countenance haggard, and expressive of severe distress; but his skin was hot; his tongue much loaded, brown, and moist; bowels not open for two days; he still said he had no cough, and complained only of pain in the side and difficulty of breathing. His respirations were 40 in the minute; his pulse 120, small, and very feeble; he lay upon his left side, and

could lie upon his back, but not upon the right side.

Physical signs.—On the left side there was a little increased fulness, but no bulging; the inferior ribs were not elevated on inspiration. Dulness on percussion existed on the left side as high as the spine of the scapula posteriorly, and anteriorly as high as the infra-clavicular region, which alone afforded tolerable resonance. The respiration was inaudible, or distant and tubular, excepting above the line of dulness, and even there was hoarse and imperfect. The voice was on this side less resonant than natural in the parts in which dulness existed, excepting over the mamma, where imperfect pectoriloquism was discovered; while in the infra-clavicular and acromial regions no peculiar modifications of the voice were perceptible. "Tactile vibration" was absent inferiorly. The impulse of the heart could not be distinguished below the left nipple, or on the right of the sternum, but was felt more distinctly and strongly than natural at the epigastrium. The sounds and rhythm were normal. The right side of the chest was resonant on percussion, but the respiratory murmur was obscured by sonorous and mucous rattles. Ordered—

C. C. parti dolent. ad ʒvj. Pil. Antim.

Opiat. c. Hydr. Chlorid. gr. j. 6tis
horis e haustu Julep. Ammon. Acetatis.

19th.—He had little sleep in the night; bowels relieved by the oil. He coughed "now and then;" tongue loaded, creamy, and moist; pain of side continued; other symptoms and signs as before.

Appl. Empl. Cantharid. magn. lateri sinistro. Pergat.

21st.—Said he felt better, and had but little cough, and no expectoration; tongue still much loaded, but moist; skin hot, dry, and pungent; pulse 120, small and feeble; bowels not open; respirations 28, easy.

The dulness was as before, excepting that anteriorly and inferiorly resonance now existed, arising probably from a distended stomach. The infra-clavicular region was still free from any peculiar morbid sound; but in the left mammary region was now heard distinct amphoric respiration, as from a large tube entering a cavity; and in the same situation was now audible a little resonant mucous rattle, approaching to gurgling, and imperfect pectoriloquism. The impulse of the heart could be felt only at the scrob. cord., where it was still forcible and rather bounding. On this day was for the first time heard a very peculiar sound in the precordial region with each systolic and diastolic movement of the heart, but most distinctly with the former. It was between a rubbing noise and that produced by a solid body striking against a cavity, and causing the agitation of a fluid mixed with gas, or the noise of fluid escaping from a bottle, with intermissions produced by the ingress of air. It might be indifferently represented in letters thus:—Bilop Bilop—Bilop Bilop—Bilop Bilop. It was very loud, most distinct below the left mamma, but audible, but with decreased intensity, as the ear or stethoscope was removed from this part in the course of the aorta, on the right side and the posterior part of the chest, and at the scrob. cordis. It was also distinctly heard when the ear of the observer was removed two feet from the chest of the patient, and imperfectly audible at even three feet. I had never heard anything exactly like it before. It might be supposed to arise from the heart striking against a cavity containing fluid and gas, the parietes of which cavity were covered with soft or plastic lymph. He had either swallowed or not preserved his expectoration, if he had any, but he resolutely maintained that he had none. A porringer was placed by his side, and particular injunctions were given that every thing expectorated might be saved, whatever, or how little soever, it might be.

Capt. Olei Ricini, ℥ss. statim. Hydrarg. Chlorid. gr. iiss. 6tis horis sumend. c. haust. Julep., Ammon. Acetatis, et Vin. Antim., Potassio-tartrat. ℞℥x.

22d.—Said he had nothing the matter with him but weakness; but the skin was intensely and pungently hot, and the tongue loaded. The bowels had been opened by the oil; the blister had healed; the physical signs were unchanged, excepting that some dulness and resonance of the voice existed below the clavicle. It was now ascertained that, so far from having no expectoration, he had brought up about three ounces in the twenty-four hours; that it was of a dirty mucous character, with little froth, resembling bad gruel, and had a very disagreeable, but not decidedly gangrenous odour

Rep. Empl. Lyttæ magn. lateri sinistro, et pergat.

23d.—Fever intense; physical signs unchanged, but he was far too ill for minute examination.

Rep. pil. et mistura 4tis horis.

24th.—Aspect very much improved; skin much less hot, almost natural in temperature; and tongue much cleaner. The left side was now dull up to the very clavicle, and the voice was very resonant below that bone. The fluid sounds were now not so marked in character, and more resembled the ordinary rubbing or scraping sounds of a roughened pericardium or pleura, but they were still very peculiar, and extensively audible.

Rep. pil. ter die. Contin. mistur. ut antea.

25th.—The cough was neither frequent nor severe, but the expectoration was considerable, dirty, frothless, and foetid. Pulse 120, feeble. Respirations 26, and easy. The heart was now felt at the right of the sternum, as well as at the scrob. cordis, where, as well as over the greater part of the chest, a rough grating sound was heard more or less distinctly, while below the left nipple the curious noise of Bilop Bilop was still audible. He had no heat of skin, and no distress of countenance; the tongue was cleaner, and moist, without any redness, but indicated the constitutional effects of the mercury. The bowels had been relaxed three or four times.

Hydrarg. c. Cretâ, gr. ij.; Pulv. Ipecac. C. gr. iij. M. ft. pulvis 6tis horis sumend. c. Mist. Mucilaginosâ.

26th.—The bowels were relaxed three or four times in the night, and, to use the nurse's expression, he seemed "very low." Mr. Stocker, the apothecary, was sent for, and ordered an opiate enema. He had no evacuation subsequently, but he rather unexpectedly expired at a quarter to 12 A.M.

Inspection, 49 hours after death.—The head was not opened. Thorax: on removing the sternum, the anterior edge of the left lung was found to extend to the right side of that bone, so as almost to conceal the heart, which was itself pushed much to the right side, the apex being opposite to the middle of the sternum. The pericardium, wherever in contact with, was adherent to the left pleura pulmonalis by pretty firm and œdematous lymph. Before it was opened it appeared distended; but on a section being made of the membrane, it seemed not to be more than two-thirds filled by the four ounces of clear yellow serum which it contained. At the bottom of this fluid was one loose mass of flocculent lymph, and upon its surface were several bubbles of gas, varying

in size from a pea to a small marble. At one spot, which was adherent to the pleura, and opposite to a cavity to be afterwards mentioned, it was very red, and appeared almost on the point of giving way. The heart itself was soft and flaccid, but in other respects, together with its valves, was perfectly healthy. The greater portion of the upper lobe of the left lung was adherent to the costal pleura by firm lymph, and, with the exception of the thin internal edge, which was white and transparent from oedema, was of a dirty greenish colour, perfectly airless, sank in water, and contained several depôts of matter of the size of peas, but no trace of tubercles. The lower lobe was anteriorly adherent to the costal pleura, to the pericardium, and to the diaphragm. On separating the adhesions to the costal pleura, the finger passed into a large cavity in the serous membrane, from which burst a large quantity of foetid gas, and dirty gruel-like serum, the amount of which had caused a considerable descent of the diaphragm on that side. The quantity of the fluid was about five pints. The surrounding membrane was covered with a thick layer of yellowish opaque-fibrinous exudation. The lower lobe of the lung contained several cavities, which were generally of the size of a bean, but two of which were as large as a pullet's egg, though irregular in form. One of these was close to the diaphragm; the edges of the other were firmly adherent to the pericardium, opposite to the apex of the heart, and to that portion of the serous covering of the organ which has been previously mentioned as being of a deep red colour. These several cavities were almost empty, and had a soft, flocculent, dirty, brownish-green lining. Their external parietes were well defined, and surrounded by pulmonary tissue, which was dark, but still crepitant. The odour was fetid, and the loose shaggy membrane of some of them floated in the pleuritic fluid, into which air blown into the left bronchus freely escaped, through the large irregular apertures thus formed. It was attempted to be ascertained if air passed from any cavity into the pericardium, by inflation of the lung. The attempt was not successful; but as it was made previously to the lung being disturbed, it is pretty certain that a great portion of the air contained in the left pleura was introduced thereto by these means. The right lung was healthy. Abdomen: The liver was large and myristicate. The kidneys large, congested, and coarse. The stomach and intestines, spleen, and pancreas, appeared healthy.

The preceding case presented many very remarkable features. Among the principal are the strange noise caused by the motion of the heart, and the presence of air in the pericardium. My colleague, Dr. Addison,

and several, but too few, of the pupils heard this noise, and agreed that they had never heard anything exactly like it before. Dr. Addison rather curiously compared it, without any communication with me, to what I had in my note-book previously represented it to be like, viz. the heart beating against a cavity containing both air and fluid. It is somewhat remarkable, that of this noise three *possible* sources were discovered after death, viz. air mixed with serum in the pericardium, gas mixed with fluid in the pleura, and a gangrenous cavity in the lung close to apex of the heart. Of these, I believe the last to have been the most probable, or the almost certain, origin of the noise; and for the following reasons:—Though no obvious source of the air in the pericardium was discovered, it may be a question for very reasonable doubt if it existed therein long before death, and if it did not escape by minute apertures from the gangrenous cavity connected with it through the spot of highly inflamed membrane. The rhythm of the heart was perfect when the noise was the loudest and most peculiar, and indeed whenever I examined it. There was none of that tumultuous action, or inequality, which would almost certainly have existed, if air together with fluid had been present in the pericardium. That the noise arose, not from the agitation of the gas and serum in the pleura, communicated by the heart through the partially consolidated lung, is rendered probable by what I have previously stated, viz. that a great portion of this air was almost certainly introduced into the pleura by the inflation of the lung after death, by the reflection that no positive indication of the existence of pneumo-thorax was discovered during life, and that, though the noise was heard in most parts of the chest, it was most loud over the apex of the heart. That it did arise from the beating of the apex against the gangrenous cavity containing air and fluid appears probable from the circumstance last mentioned, from the exact resemblance it had to a noise arising from such a cause, and from this supposition being consistent with all the other signs and symptoms presented by the disease. It may also be worthy of notice, that the gangrene did not affect that portion of the lung which was most inflamed, but that which was most compressed by the fluid. I mention this, not because I believe that pneumonia never gives rise to gangrene in persons who are low and wretched, and nearly starved by cold and abstinence, but because I think that, in this case at least, it probably arose from the supply of blood being partially cut off from the lung of a person already much reduced by his disease, that lung being prevented from collapsing by old and firm adhesions to the costal and phrenic pleura.

If this view of the cause of the gangrenous cavities is correct, it may be questioned if it would not have been advisable to have tapped the chest. I think it would certainly have been a proper plan of treatment to have been adopted; and I was constantly upon the watch for a favourable opportunity, as regarded the condition of the patient, of having the operation performed. Unfortunately no such opportunity appeared to me to present itself. The man probably ultimately died from the escape of air into the pericardium.

CASE VIII.—*Phthisis—Pneumonia—Empyema—Pneumo-thorax?*

(I lament that this case is in every respect defective. I took no notes of it myself, and am indebted to the public records of the hospital and my own memory for the few particulars detailed.)

W. L., aged 25, a shoemaker, residing in Bermondsey, of small and delicate frame and sickly aspect, presented himself to me among the out-patients of the hospital, Nov. 23d, 1842, but being exceedingly ill, was taken in and placed under other care. He stated that he had been in the habit of working in a damp room, and that he was first attacked with pains in the limbs, followed, in about nine days, with hoarseness and cough. In one of his attacks of coughing he expectorated a tea-cupful of bright frothy blood. His mother died of an affection of the chest, accompanied with cough. A fortnight previously to his application he had been seized with pain of the chest. He had lost flesh, and perspired at night. On admission he was affected with pain of the back and left side; frequent cough, with expectoration of muco-purulent matter mixed with blood, and considerable dyspnoea. The whole of the chest was rather dull on percussion, but this dullness was particularly remarkable in the lower part of the left side, anteriorly and posteriorly. Cavercous respiration and gurgling were audible over the left mammary region, and muco-crepitating rattle throughout the greater part of this side posteriorly; but both at his admission and during the few days he afterwards lived, he was in too feeble a state for minute physical examination. He constantly lay upon the left side. In the notes of his case I perceive nothing particularly worthy of notice till his death, Dec. 6th, except that he continued to complain of pain in the left side, that he perspired profusely, and that the expectoration became purulent, and "left the side of the vessel in a mass."

Inspectio cadaveris, 32 hours after death.

—On removing the sternum a cavity was laid open in the mammary region as large as half a foetal head: it appeared perfectly circumscribed by the surrounding adherent pleura,

was crossed by bands, and lined with loose opaque fibrin, but its connexion with the bronchial tubes was unfortunately not examined. The pleura, in a sac entirely unconnected with the cavity just noticed, contained a pint and a half of puriform fluid, and was at other parts covered with a pale dense and thick new membrane. The lung itself was sprinkled with large opaque white tubercles, and was in different parts firm, watery, or purulent, from a low form of pneumonia. The right lung was firm and oedematous. The heart was natural, and nothing remarkable was discovered in the abdominal viscera.

I have introduced this very imperfect case solely on account of the cavity in the mammary region, which I believe to have been a defined pneumo-thorax, accompanied during life with all the signs of a phthisical cavity. Its especial relations with the pleura and with the bronchial tubes were unfortunately not minutely investigated, and I am therefore unable to pronounce, with absolute certainty, that my belief was founded on fact.

CASE IX.—*Phthisis—Pneumo-thorax?—Empyema?*

J. D., aged 28, admitted into Guy's Hospital, August 2d, 1843, under the care of Dr. Babington. He formerly carried on the business of a sail-cloth maker in the country, and was at that time in the practice of drinking pretty freely of gin and water. His subsequent occupation as an inn-keeper at Islington, probably tended but little to the diminution of this habit. To the cold and damp cellars of his establishment he attributed the origin of his present illness, during great part of which he had been confined in the Queen's Bench Prison: he was thence removed to the hospital. He had lost one brother at the age of 50, but he had a father, mother, two brothers, and one sister, still alive, and in good health. For the last two winters he had been troubled with cough for six or eight weeks, but he had hitherto always lost it during the summer. On admission he was pale, thin, and freckled; of light complexion, and about 5 feet 10 inches high. For the last three months he had been more or less troubled with rheumatism, and four weeks since he had a severe pain of the left side, since which his cough had been less frequent and troublesome. He had at no time any large amount of expectoration, nor did he remember ever having been attacked with sudden and violent dyspnoea. He lay on his back, with his shoulders slightly elevated, and the body rather turned to the left side, but he could lie without inconvenience upon either side, or perfectly supinely. He had but little cough, and his expectoration was scanty, thick, muco-purulent, and destitute of air-bubbles. He talked freely, and sat up in bed without dis-

tress. The skin was natural, and he said he did not perspire except in very hot weather; the pulse 120, very small and feeble; the respirations 26, and perfectly easy; the face and body were emaciated, the countenance expressive of care, the tongue clean and moist, and rather pale. *Physical signs.*—Some flattening existed below both clavicles, but the form of the chest was not otherwise abnormal; no enlargement or bulging was perceptible. The right side sounded generally pretty well upon percussion, and the respiratory murmur was no where deficient, though at some parts it was puerile, and in others hoarse and rough. The infra-clavicular, and upper part of the mammary regions of the left side were more resonant than natural, but not tympanitic upon percussion; and in the recumbent position there appeared little or no dullness anteriorly, even at the lowest part of this side of the chest. Posteriorly dullness existed as high as, or above, the inferior angle of the scapula. The respiratory murmur was imperfectly audible both before and behind at the upper part of the left side, but near the nipple the breathing was occasionally fistulous, with a metallic ringing. This was not observed to accompany the voice or cough. Posteriorly and inferiorly the respiration was either entirely absent, or distant and indistinct. There was not at this part resonance of the voice or tactile vibration. About the lower angle of the scapula, Hippocratic succussion was easily and constantly produced by shaking the body. I had many opportunities, by repeated experiments, of verifying these signs, which never materially varied. He died, rather unexpectedly, August 14th. The inspection of the body was not permitted.

As the body in this case was not examined after death, it cannot be asserted, positively, that it was one of pneumo-thorax and empyema. I have, therefore, inserted a note of interrogation after these terms at its heading. I believe, however, there was at the time but little if any doubt upon the subject. If the presence of this affection is assumed, the case presents a striking instance of the absence of the marked symptoms which often accompany the first formation of the complaint; as the patient stated, after repeated examinations, that he had never been suddenly seized with dyspnoea or collapse, and it was almost accidentally that some of the most marked signs enumerated were discovered at the first visit. The side was not enlarged, there existed no tympanitic resonance on percussion, and, except where the presence of fluids was clearly indicated, the respiratory murmur was not altogether absent. If the case, on the contrary, be regarded as one of simple phthisis, then it presented the still more

rare phenomenon of Hippocratic succussion in a phthisical cavity.

CASE X. — *Phthisis — Pneumo-thorax — Empyema. — Death after about two months.*

(For the previous history of this case I am indebted to Mr. Arnold, the industrious clerk of the ward.)

H. S., aged 26, stated to be a widow without children, admitted into Guy's Hospital, Sept. 13, 1843, under Dr. Babington, but during his absence from illness placed under my care. She was of fair complexion, with light hair, and had always been "delicate." She had lived loosely and intemperately, had ulcers on the legs for the last two years, and for the last six months had been greatly dejected in spirits, from having been deserted by a person with whom she had previously cohabited. She had been treated for hysteria. About six weeks before her admission she had severe shiverings, followed by heat of skin, thirst, sore throat, cough, difficulty of breathing, and pain of the chest, many of which symptoms had continued with greater or less severity up to that time. She came to the hospital for advice till five days before, when she was suddenly seized with violent dyspnoea without pain, and had since been confined to bed without medical assistance. When first brought to the admission-room she was pale and faint, and breathed with such evident distress as to lead me to say, "that person breathes like one suffering from pneumo-thorax." I ordered her to be put to bed immediately, but had little thought that the supposed resemblance would prove to be a reality. When first visited her face was bedewed with perspiration, her extremities clammy, and her dyspnoea was extreme. She was exceedingly faint; the pulse was so feeble and frequent as not to be counted, and the distress so great as utterly to preclude any examination: she was therefore ordered some wine, and to be kept perfectly quiet. When seen two hours after, she had rallied a little, and was lying on her right side. Her respirations 40 and anxious, her pulse 120, and very small and feeble. The extreme distress previously exhibited by her countenance had in a great measure disappeared, but she could, even then, not speak above a whisper. She had no pain, very little cough, and scarcely any expectoration; the very trifling quantity seen was muco-purulent; the tongue was rather dry, and brown; she complained of thirst, but had no vomiting or flatulence; the bowels were rather relaxed; the catamenia, previously profuse, had been altogether absent for the last two months. *Physical signs.*— Huge pendulous mammae, reaching nearly

the umbilicus, and still urgent distress, prevented any minute examination. The ribs on the left side were alone elevated upon inspiration. Percussion elicited a dull sound over the whole of the left side anteriorly, and over the infra-clavicular region of the right side; the latter was preternaturally resonant under the mammaræ and in the axillary and lateral regions. Both sides were moderately and nearly equally resonant posteriorly, conceding on the right some dulness, on account of the liver. Throughout the whole of the left side, anteriorly, were heard mucous rattles, which below the clavicle approached the character of gurgling. Posteriorly, on this side, sonorous and sibilant rattles were chiefly audible, mixed at some parts with pure bronchial respiration. The respiratory murmur was absent over the whole of the right side. Some bronchial breathing was alone audible in the acromial-scapular and infra-clavicular regions, and close to the dorsal spine. At other parts, and particularly posteriorly, was heard shrill metallic respiration, but no distinct tinkling. The cough and voice, as far as she was capable of exciting the one or of employing the other, were purely metallic. Hippocratic succussion was very evident. These signs were gradually and slowly elicited, as her strength would permit. Ordered—

Julep Ammoniac, 4tis horis; Ext. Hyos-ciani, gr. v. hora somni; Wine, ʒiv. or vj., as required, Good beef-tea and arrow-root. Perfect rest.

By the employment of these means she rallied surprisingly, and though, when recumbent, she constantly lay upon the right side, she was able to sit up in bed without distress; colour returned to her cheeks; her countenance lost much of its anxious expression; the cough was far from severe, the expectoration trifling, and the respiration no longer laborious. Physical signs unchanged. By the aid of a pill containing a quarter of a grain of muriate of morphia, she slept well at night.

Sept. 28th.—She lay the whole of last night upon her left side, and at the visit was sitting up in bed and looking cheerfully. The breathing was not now anphoric, but the voice and the cough still had a metallic resonance, and the splashing on succussion was still distinctly audible. Harsh respiratory murmur, with bronchial respiration, was now heard in infra-clavicular, acromial, scapular, and inter-scapular regions. The dulness and mucous gurgling of the left side had much decreased. She slept well, and had some appetite. Ordered—

Decoct. Cinchon. Julep. Ammoniac, aa ʒvi. ter die. Rep. Pil. Wine as before, and a mutton chop.

Oct. 10th.—She had been going on quietly, was cheerful, sat up in bed, and for a part of several days past had been dressed and sitting by the fire, though her breathing was rendered difficult by motion. She had scarcely any cough, and lay occasionally for the entire night, without distress, upon the left side. An attempt was made to measure the chest. This I have always found to be difficult to effect with exactness, but the immense mammary appendages to the chest in this instance caused much additional obstruction. The right side, upon inspection, seemed to be certainly not larger than the left, and was supposed to be found by ad-measurement $1\frac{1}{2}$ inch less. This, however, I believe, could not be trusted, and it was proposed to be attempted at a future time, but as the patient objected, and desired “not to be pulled about,” the intention was never fulfilled. She continued for many weeks much in the same state. I saw less of her, in consequence of her physician, Dr. Babington, having resumed his duty, but I ascertained that the symptoms and local signs continued, without much alteration, till about two weeks before her death, when she became more distressed in mind and body, and complained of pain in her left temple. For this a few leeches were ordered, without benefit, and her wine, which had been previously discontinued, was afterwards restored without advantage. She now began gradually and slowly to sink, and her dyspnoea increased very considerably. She complained of pain in the left side, but said it was not severe. On the morning of Nov. 18th, nine weeks after her admission, after taking her breakfast as usual, she was found dead in her bed. She was at first supposed to be asleep, so quietly had she expired.

Inspection, 53 hours after death.—I was not present before the body was opened, and the sides were unfortunately not measured. The head was not opened.—*Thorax:* On the scalpel entering the right pleural cavity, fluid and a little air escaped with great force and noise. Two quarts, at least, of thin cream-coloured fluid were found in the right pleura, and the lung was thereby much compressed towards the spine, and the mediastinum pushed to the left side. The serous membrane, excepting at the apex, where it was adherent, was every where covered with a thick layer of yellowish-white fibrin, which was soft and flocculent externally, but firmer and smooth near the pleura. No aperture was visible in the pleura, nor could any be discovered till the lung was removed entire and inflated under water, when a small pin-hole opening was found, which communicated by a tube of fibrin about a quarter of an inch long, with an irregular cavity as large as a nutmeg close to the sur-

face of the serous membrane. The cavity, situated quite at the lower part of the upper lobe, had a soft, loose, yellow lining, and was entered by a bronchial tube as large as a crow-quill. The surrounding lung, to the size of a pullet's egg, was firm from old pneumonia and tubercles. No other cavity was discovered. The other parts of the lung were scantily sprinkled with opaque tubercles. Most parts were pretty crepitant and distensible by air, and no part was absolutely solid except that around the cavity. Many of the bronchial tubes were largely dilated. The apex of the left lung was adherent and consolidated, from old pneumonia, all activity in which had ceased. As the probable results of inflammation, however, had been left several portions of opaque, white, firm, and even hard, serofulous matter, as large as peas, in separate and agglomerated masses. The remainder of the lung was affected with slight recent pneumonia. The pericardium was healthy. The heart was rather pale, loose, and flabby; its valves were not diseased, nor were its cavities dilated. In the apex of the right ventricle was a firm mass of leathery fibrin, which appeared to have been formerly hollow, and to have contained fluid which had escaped, and thus allowed of the collapse of the cyst. Other small detached masses were confined by the bands of the muscoli pectinati. — *Abdomen*: The stomach was red, tumid, and ulcerated. The liver was large, partly coloured, soft, and fatty. The kidneys were firm and coarse, and their tunics adherent.

The history of this case is somewhat doubtful and obscure, as the patient had been supposed to be suffering from hysteria alone before her admission. By whom she had been prescribed for, I could not ascertain, but I distinctly found out that she had not been seen by any of the professional officers of the hospital. What had really been the train of previous symptoms could not be accurately determined, and the period of the escape of air into the pleura could not be defined with any thing approaching to certainty. It might have been five days before her admission, when she was stated to have been seized with sudden and violent dyspnoea; but even upon this point the patient and a constant female attendant varied considerably in their representations. It might have been on the very day of her admission, when the distress was extreme. If the latter supposition was correct, then it is almost certain that pleuritic effusion had previously existed, though not in sufficient quantity seriously to embarrass the respiration, or compress the lung; as, on the day she entered the hospital, she was affected with all the symptoms, excepting pain of the side, which Louis has supposed (but as I conceive incorrectly) always to ac-

company the escape of air into the pleura. The aperture in the pleura was very small; the cavity in the lung with which it communicated was small also; the lung was comparatively slightly diseased; few or not extensive adhesions existed; the distress and dyspnoea, on admission, were excessive. The aperture, indeed, was so small that it required all the delicacy and perseverance of my friend, Mr. Hilton, even with the aid of the blow-pipe, to detect it. Had not the blow-pipe been employed—still more had not the untiring energy of such an individual as Mr. Hilton been exercised—would not this case have been put down as “a remarkable instance of the secretion of gas by the pleura?” I believe that it most certainly would have been so recorded. The patient probably ultimately died from the serous effusion into the pleura, and possibly might have been temporarily relieved by paracentesis thoracis, had she been considered in a fit condition to undergo the operation.

[To be continued.]

ON THE STATISTICS OF FEVER IN ST. THOMAS'S HOSPITAL;

WITH REFERENCE TO TREATMENT.

By H. BURTON, M.D.

(For the *London Medical Gazette*.)

[Continued from page 210.]

Day of fever.

In speaking of the termination of fatal fevers relative to the day of commencing their treatment in hospital, I may in the first place remark that the histories of the epidemic fevers which existed in early times, and the numerous records of their more recent occurrence in localities remote from one another, furnish sufficient support to the opinion of the probable continuance of an universal and variable, but constant rate of mortality from this source, and that the healing power of physis is controlled by causes the fatal influence of which can never be entirely obviated by medical art.

But although an uncertain number of fevers must inevitably prove fatal, there is no reason to question the salutary influence of medicine over a multitude of cases which terminate in recovery; on the contrary, ample evidence is afforded of its utility by daily experience, and of the probability of many fever patients having been preserved by timely and judicious treat-

ment. These remarks apply particularly to patients in hospital, where their wants can be properly satisfied, and the requisite attention strictly enjoined to ventilation and cleanliness, but which cannot be insured at the squalid homes of the poor, and amidst the unavoidable privations of poverty. The efficacy of treatment in fevers removed from the pestilential abodes in which they were engendered, to the airy wards of St. Thomas's, is continually evinced by its beneficial results, and in confirmation of its greater efficiency also in the St. John's Fever Hospital at Limerick, I again refer to the "Report" of Dr. W. J. Geary (Dub. Med. Journ. vol. 12, p. 385), in which the average mortality among fevers treated in hospital during five years is stated to have been annually considerably less than the mortality among fevers treated also by Dr. Geary, during the same five years, at the patients' homes. The same author also very judiciously lays great stress upon the importance of the early commencement of treatment in fever, and as far as I have been able to compare the results of his experience with my own, they correspond very nearly with those derived from the treatment of the fevers enumerated in this paper. There can be little doubt, for several reasons, that the influence of the day of commencing treatment ranks high among the various and subtle causes which modify the mortality; and as an index of the progress which the febrile poison has made in raising obstructions to the functional acts of the vital organs, it deserves, as regards prognosis and therapeutics, an attentive consideration. In reference, therefore, to this important topic, I propose to inquire: 1stly, into the influence of the day of commencing treatment, on the rates of mortality. 2dly. Its influence on the duration of fatal cases. 3dly. Its influence on the duration of cases which terminated in recovery.

1stly. Among the 35 fatal cases enumerated in table I, there were 20 in which a relation was observed between the day of fever on admission and termination; in 14 cases the day of fever was either unknown or the disease had existed above a fortnight, and in one case the patient recovered from fever, and died of a chronic pulmonary disease.

This series would be justly considered too limited to afford satisfactory results, if viewed unsupported by evidence obtained from other sources, but as my results correspond in all essential respects with those deduced from a much more extended series furnished by Dr. Geary, its extent is, I think, adequate to afford, with a near approach to accuracy, a true average relation between the days of commencing treatment and the rates of mortality among the fevers admitted on each day respectively into my wards. As regards the question of critical days in fever, it is worthy of remark, that in Dr. Geary's Report, the mortality is represented to have been greater among the cases which were admitted on the 7th day, than on any previous day; and greatest after the 14th day, among 3298 cases. But the rates of mortality among fevers admitted between the 7th and 14th days varied irregularly with the advance of the disease; the mortality for instance, among patients admitted on the 7th day, was greater than that on the 8th, 9th, 11th, and 14th days; and the mortality on the 12th day, although greater than that on the 7th day, was less than among patients who were admitted on the 10th day of the fever. Hence, no invariable proportion seemed to exist between the daily rates of mortality, and the day of the disease after the 7th day, among Dr. Geary's patients; neither was there any to be observed among my own; but on the contrary, analogous variations were noticed, and in very many cases of fever it was impossible to ascertain within a day or two the exact period at which the disease commenced; hence, as a brief delay of a day or two in commencing treatment after the first week of fever has not been shown to affect its fatal termination in any regular order, I have calculated the average rates of mortality for each week after the following manner. (See top of next page.)

The two foregoing series of ratios do not differ materially from one another, and both of them show that the mortality was least among the patients admitted during the first week, and greatest after the second week of the fever. This close correspondence between two independent series of observations leaves no room for reasonable doubt as to the general accuracy of both; and the facts which they deve-

lope suggest at once the reflection, that had the patients who were admitted during the second week, and subsequently been received into hospital during the first week of their respective fevers, the mortality among the total number would have been considerably less, and many lives saved.

It is by first estimating truly the causes which modify the rates of mortality from fever, that we can hope eventually to reduce them to their lowest limits, and as the virulence of the febrile poison is increased by the neglect of prophylactic measures, and its infecting power consequently augmented, another reason is adduced in favour of the speedy removal of the patient from the vitiated atmosphere of his home, to the well-ventilated wards of a hospital, where appropriate means are taken, by which the diffusion of typhus is checked, and the mortality from it materially diminished.

In pursuing our inquiry as to the influence of the day of commencing treatment on the mortality from fever, and its duration in fatal cases, as well as in recoveries, the agency of organic disease and that of the febrile poison considered as an entity, but without respect to its essential nature, will appear to exercise a strong controlling power which should not be overlooked. To the existence of organic disease, either confirmed before the accession of fever, or caused during its progress, may be ascribed, in part at least, the greater mortality represented on table 3, to have taken place during the two coldest quarters of six years when the inclemency of the seasons, which is experienced by patients who resort to hospitals far more severely than by others in comparatively easy circum-

stances, was likely to have excited acute inflammations in some of my patients, and have aggravated the infirmities of others. The coexistence of organic disease and recent congestion has been often noticed at post-mortem examinations by different physicians, but my own notes of the morbid appearances observed in bodies of fever patients are scanty, and their defects induce me to supply the requisite information from a copious and lucid description given by Dr. Reid in the *Edin. Med. Jour.* Vol. 52, pp. 448, et seq., of the lesions observed in 47 bodies dead of a similar fever at the Royal Infirmary, Edinburgh, in part of the years 1838 and 1839, when continued fever was epidemic in that city. Dr. Henderson has given in the same Report, pp. 429, et seq., a detailed description of its symptoms, and as they were chiefly referrible to the brain and lungs, and less obviously to the alimentary canal, the type of fever seems to have nearly corresponded with that contemplated in this paper. In all my own fatal cases stupor was more or less profound, either on the day of admission, or a few days after; the other symptoms were not equally obvious. In three the stupor was profound, and they terminated on the day of admission, or the next; in 16 out of 35 cases, the stupor was associated with great pulmonary obstruction; in three with retention of urine; in three with diarrhoea; in one with vomiting, in another with tympanitis, and in five with severe abdominal pain, which had appeared at an early period of the fever.

In reference to post-mortem appearances, Dr. Reid says (pp. 448, et seq. *ibid.*), that lesion of the alimentary canal has been comparatively rare in

the fever of Edinburgh for several years, at the time he wrote, and in only 2 cases out of 43 examined by him were the elliptical particles of Peyer very distinctly elevated, and presented any appearance of ulceration, although in 24 they were apparent and distinctly defined. In most cases the blood-vessels of the brain were loaded with blood, and in one half serum was effused within the cranium; the lungs also were either more or less gorged with blood and frothy serum, or consolidated, and the seat of chronic disease, in about 34 out of 44 cases.

I have extracted the above remarks from Dr. Reid's valuable Report, in evidence of the general nature of the lesions which were suspected to predominate in all my cases, and to be analogous to those seen by me in a few; and as the complications on the day of admission varied in my cases, they should be taken into calculation with reference to the influence of the day of commencing treatment on the duration of fatal fevers.

2dly, *Day of fever on duration in fatal cases.*—It is probable that the rates of mortality are modified not only by the co-existence of organic disease with fever, but likewise more especially by the mutable virulence of the febrile poison, and the vital importance of the organ on which its principal action is exerted; and as it is generally admitted that diseases of the alimentary canal accompanied with fever are not so immediately subversive of life as those of the brain and thoracic viscera, there is reason to infer, that when symptoms predominate which are referrible to the abdominal canal, the fever, although ultimately fatal, may linger on for a longer period than where they are referrible to more important organs. And accordingly I think the variable length of the fevers enumerated in the following table may be partly ascribed to these causes, and partly also, though less obviously, to the day on which the treatment was commenced.

In reviewing the preceding results, a

distinction should be made between the duration of fever after admission,

and of that from its commencement, for a comparison between the two in-

tervals will show that the two intervals do not bear any constant or regular proportion to one another; on the contrary, it will be seen that, whilst the utmost difference between the average duration after admission among Dr. S. Smith's cases amounts to only 4 d. ys., the utmost difference between the average duration of them from their commencement exceeded 15 days, and the differences between the two intervals, in the three weekly periods, were respectively 6 days for the first week, 9.8 days for the second, and 20.2 days for the third week. Similar differences, although less in amount, will be observed in the series derived from the three other sources named in the table, and it is also interesting to observe, that notwithstanding the length of the fevers at Paris from their commencement, and which were admitted during the two first weeks, exceeded the length of those treated in London during the same periods of the disease, yet in both cities the fevers admitted in the first week terminated sooner than those admitted in the second week; a correspondence which seems to bear a relation to the question of the "identity or non-identity of the continued fever of France and England," very ably discussed by a contributor to the 12th volume of the Brit. and For. Med. Rev. pp. 294, et seq. It leads also to the conclusion that fatal fevers in general are protracted in proportion to the times at which their treatment was commenced. This anomaly may, I think, be in part ascribed to the variable activity of the febrile poison, and the vital importance of the organ on which its power is chiefly exerted: thus, among Dr. S. Smith's cases there were 54 in which the fever was complicated with cerebral, thoracic, and mixed, and 25 cases chiefly with abdominal disease. Now, without reference to the periods at which they were admitted, I have calculated the average duration of these 25 cases to have been 26.4 days; and that of the 54 cases 20.4 days; hence the difference of 6 days between these terminations may be ascribed, *ceteris paribus*, to the influence of organic lesion, and the virulence of the febrile poison. This inference derives support, also, from the fact that the 9 cases treated by myself in the first week of the disease

having been for the most part complicated with cerebral disease only, the average duration of which was only 12.6 days, or 7.8 days less than that of the mixed diseases, and 13.8 days less than that of fever with abdominal disease. Besides, the duration of 12.6 days observed in the cerebral fevers at St. Thomas's, corresponds very nearly with that given by Dr. Reid of 43 cases of fever examined by him *post-mortem* in the Royal Infirmary, Edinburgh, the average duration of which was only 12½ days; and as the fevers described by Dr. Henderson and Dr. Reid were supposed to be similar to those admitted into St. Thomas's, I think the variable duration of fatal fevers should be ascribed to the vital importance of the organ implicated, rather than to the influence of the day on which their treatment was commenced. Upon comparing the symptoms, history, and treatment of the fatal cases in my practice with those of the severe cases apparently similar, but which terminated in recovery, I could not discover any adequate reason why one patient should die and the other be restored to health; and as an analogous obscurity may be supposed to have concealed the relation between cause and effect from other physicians, the variations alluded to cannot, I think, be traced to the nature of the treatment which was adopted. But although it seems to fail in regulating the duration of fatal fever, yet the results represented on Table VII show that the mortality from fever is fearfully increased by delay in commencing treatment; and evidence will presently be adduced to prove that convalescence is established on an average between 5 or 6 days sooner among those who are admitted in the first week, than among those in the second week of fever.

3dly, *Day of fever on duration in recoveries.*—With reference to the object of this section, I have collected the data furnished by my notes of 109 cases of adynamic fever of variable severity which were admitted between January 1837 and May 31, 1838, when the disease was epidemic in the metropolis, and the following arrangement shows the relation between the day of fever, the cases admitted, and its average duration respectively on each. (See top of next page.)

For the sake, also, of verifying and

TABLE IX.

Day of fever when admitted	3	4	5	6	7	8	9	10	11	12	13	14	Over	Total.
Number of cases on each day	3	3	6	7	27	6	10	11	2	3	0	24	7	109
Duration of fever from its commencement	17	18	20	20	22	23	29	25	21	24	0	27	36	

comparing the foregoing results with others deduced from data collected on the decline of the epidemic, I subjoin a second series of 114 fevers, mixed as

regards their severity and complications, sex and age, and which were admitted between May 31, 1833, and Jan. 31, 1842.

TABLE X.

Day of fever when admitted	3	4	5	6	7	8	9	10	11	12	13	14	Over	Total.
Number of cases on each day	6	4	7	6	28	11	4	7	5	3	0	25	8	114
Duration of fever from its commencement	14	15	20	23	21	19	25	36	24	22	0	27	35	—

The results exhibited on both tables shew that the average duration of fever increased, although irregularly, with the day on which its treatment was commenced between the 3d, and beyond the 14th days; and that the patients who were admitted on the 7th day recovered nearly a week sooner than those admitted on the 14th day; and between 14 and 15 days sooner than those admitted after the 14th day of the fever. The results are particularly interesting, as proofs of the great importance of commencing treatment at an early period, and, in conjunction with those enumerated on Table VII., they strengthen the inferences before noticed, that the mortality from fever, as well as its duration in recoveries, might be lessened by the timely application of therapeutic measures.

As regards the term "*duration*" of fever which terminates in convalescence, it is proper to remark that hardly any phenomenon relating to the form under contemplation is more variable than the period at which febrile action ceases, and the apyretic state is estab-

lished. In explanation, therefore, of the meaning attached to this term by me, I beg to refer to page 205, MED. GAZ. vol. xxxiii., where the manner is described in which the continued fevers of the last six years were for the most part observed to terminate in convalescence: but to avoid ambiguity, I may add here that the increasing desire for food usually corresponded with the gradual disappearance of the febrile symptoms; and that three or four days were allowed to intervene between the day on which they were supposed to have entirely ceased, and that on which the diet was changed; the term, therefore, "*duration*," in this paper, strictly signifies the day on which the patients were considered by me to be able to digest solid food, after having been restricted to the use of diluents, arrow-root, bread, and beef-tea. The days on which this change of diet was prescribed were marked in my ward-books, and although, perhaps, the change was sometimes delayed unnecessarily, yet these delays were not sufficiently numerous to affect the average results of

treatment represented in the preceding and following tabular arrangements; in all of them the duration of the fever is calculated from its commencement before admission to the day on which this change was made after admission into hospital; and hence the results represent the therapeutic rather than the pathognomonic duration of the disease. The test of returning appetite was also considered by M. Louis as a proof of the termination of the fever in Paris; and at p. 12, t. i. in a footnote, he observes, "Jemets l'époque de la convalescence au moment où les malades ont commencé à manger un peu de pain." The regularity which attends the course and duration of exanthematous fevers, such as variola and rubeola, is not so obvious in the continued fever under contemplation, and which my friend Dr. R. Williams justly states, "runs a course of very varied length" (*Elements of Medicine*, vol. i. p. 25); a length that extends, according to Dr. Elliotson, from one day to eight or ten weeks (*Principles and Practice of Medicine*, p. 259), and to Dr. Tweedie, from one day to two weeks, or the beginning of the third week (*Cyc. Præ. Med. art. Fever*, pp. 158, et seq.) The variations are attributed by these, as well as other authors, to different causes, but in particular to the complication of fever with organic disease: and in the *Brit. and For. Med. Rev.* No. xxiv. Oct. 1841, p. 320, the mean duration of fever complicated with dothineritis in 255 recoveries, is stated by Dr. Jackson to have been 22.019 days: but during the epidemic fever at Edinburgh in 1838 and 1839, when dothineritis did not generally prevail, Dr. Henderson (*Edin. Med. and Surg. Journ.* vol. xl. pp. 445 and 446) says the average duration in 23 cases that were bled was $11\frac{2}{3}$ days, and in 24 cases that had wine 15 days, to the commencement of convalescence. In 88 cases treated at Paris by M. Louis between 1820 and 1827, the average duration was much longer, and extended to between 31 and 32 days (*Recherches sur la Gastro-Enterite*, pp. 468, 469, tom. ii.), a period almost precisely equal to that at which 10 fevers with abdominal complications, described by Dr. Bright (*Medical Reports*, vol. i. p. 201), recovered in Guy's Hospital during the years 1826 and 1827. But this latter duration exceeds that of 14

mild cases treated by M. Andral at Paris during the same years nearly, and which the latter physician states was only $18\frac{1}{4}$ days (*Malad. de l'abdomen*, tom. i. p. 330, et seq.)

The above quotations will convey a sufficiently distinct notion of the variable average length of continued fever, and will serve also to suggest the propriety of avoiding any positive expression of opinion as to the exact period at which convalescence will begin in any single case; for although Dr. Holland truly remarks, at p. 6 of his "Medical Notes and Reflections," that errors are, in reference to pathological results, best corrected by numerous and repeated averages," yet the wide latitude between the two extremes of a series constructed in reference to the duration of fatal fever, as well as of recoveries, materially diminish the value of average results of treatment to the practical physician. But notwithstanding the uncertainty which prevails on this point, a nearer approximation to a definite period may, perhaps, be made by allowing for the agency of those causes which have been already noticed as most obviously modifying the mortality from fever, and which may be supposed, with equal reason, to cause a variation in the period at which convalescence begins.

Influence of sex in recoveries.—Under this impression, and with the view in the first place of ascertaining how far difference of sex influenced the duration of the cases treated by me, I have enumerated, in the following table, the days on which respectively, after admission, 144 male and female patients returned to a meat diet, between the 1st June, 1838, and the 31st Dec. 1842. (See Table XI.)

The total numbers of the two sexes were almost equal, and nearly an equal number of each returned to a meat diet about the same periods from the commencement of their respective fevers; the greatest difference occurred among the cases of the second week, in which it will be seen the excess was on the side of the males, and amounted only to 9 between 45 and 36 females; but that difference exceeds the proportional difference between the total numbers of the two sexes by only rather more than 1, and is compensated for by the excess on the side of the females admitted in the fourth week.

TABLE XI.

Periods from the commencement of fever at which 114 patients returned to a meat diet.		Number of weekly returns.		Differences.	Total returns.
		Males.	Females.		
From 4 to 7 days .	First week . .	15	14	+1 m.	29
8 to 10 days }	Second week }	14	14	0	81
11 to 14 days }		31	22	+9 m.	
15 to 21 days .	Third week . .	13	14	+1 f.	27
Over 21 days . . .	Fourth week .	2	5	+3 f.	7
Totals	—	75	69	+6 m.	144

From another calculation, I found the average time, after admission in 1838, at which 29 females returned to a meat diet, was 13 days, or about three quarters of a day sooner than 23 males of the same year and seasons. Sex, therefore, appears to exert only a slight influence over the duration of fever,

after admission, in recoveries; and the same remark applies to its agency in fatal fevers, although, on reference to Table V., the proportional mortality among females is represented to have been much less than among males in St. Thomas's Hospital.

Hermaphroditism: a Memoir read to the Royal Society of Edinburgh in 1827 and 1828.

PART V.—CONCLUSION.

I HAVE thus endeavoured to shew, that in the construction of the generative system of organs of the animal kingdom, nature had in contemplation a plan sufficiently comprehensive to embrace all the forms and combinations of organs which the œconomy of any animal, its destination, its habits and mode of existence, its relations to the external world, and to others, whether congeneric and of the same species, or specifically and generically distinct, might ultimately demand or render essential. But of these modifications there was one, viz. that some animals should carry within them the organs we denominate male and female, and that others should have them distinct. Now in the construction of the whole species the type was uniform as to both sets of organs, and in the construction of the great group of the vertebral kingdom

the type in like manner was uniform, and both sets of organs given to all. This superabundance in nature's works, this prescience or forethought of all that could possibly be required in structure, accords better with the other phenomena of the material world—a superfluity, rather than a scarcity. It accords with what we know of the enormous superfluity of the seeds of all vegetables with which the world abounds, and with the numerous remains of rudimentary structures crowded occasionally into the structure of animals whose œconomy is entirely adverse to their developement. This great law, should it ultimately receive the sanction of time, sets aside all those metaphysical speculations on which have been founded doctrines of analogies, and the extraordinary doctrine, that nature, in selecting a type or model for the animal kingdom, had selected the most simple instead of the most complex; thus forcing the human embryo to pass through those gradations, or rather I should say degradations, embracing within them the whole range of the animal creation.

This great step led naturally to the inquiry as to the nature of the rudimentary organs; such as the presence of the swimming bladder of fishes, and the double organs of the protens and syren, and axolotl, the difficulties in the explaining of which had been got over by a recurrence to the old law,

that all animals were forced to pass through the same laws and structure; and if remains of branchial organs were found in animals whose economy ultimately demanded and required a pulmonary system of breathing, it was said that the animals had to pass in their fetal state through an ichthyological structure, and that this was the reason why rudiments of such organs were present in the adult; but if man were forced to pass through this ichthyological state, it is difficult, if not impossible, to imagine the necessity for fishes having rudiments of pulmonary organs; inasmuch as they do not at any period of their existence enjoy a pulmonary system of breathing. Those great observers who have denied that nature ever created any structure purely ichthyological or ornithological, were undoubtedly correct in the principle; but when it was attempted to be shewn, that out of the same elementary parts nature had constructed both sets of organs, when the pulmonary system was supposed to be repeated in the branchial, then assuredly, like an erroneous calculation in algebra, the deeper and more sweeping the calculation, the further the inquirers diverged from truth. In the determination of the skeleton of the vertebrate animals, I shall take occasion to call the attention of the Society to these great questions, early in the following session.

The definition usually given of hermaphroditism is quite arbitrary: nor do I believe that in the animal kingdom there actually exists any true hermaphrodite accordant with the vulgar definition of this word. Many animals have both sets of organs, but for the perpetuation of the species they constantly require the co-operation of another individual. Cavolini imagined hermaphroditism complete in all respects to exist in certain fishes, but no proofs have ever been fairly brought forward so as to satisfy all doubts*. We dismiss,

then, the question as to the possible existence of hermaphroditism in the vulgar sense, by supposing that no such state ever existed in any animal.

Modern laws, I presume, do not recognise hermaphroditism, and yet, by the Roman and French law, as quoted by Bauhin, in his work on hermaphrodites, these beings are required to employ the organs of one sex only. This seems to imply that the compilers of these laws believed in the existence of these compound heterodoxical beings: but we need not, for all this, attach the slightest value to the collective wisdom of legislative bodies, whether Roman or French, for the same statutes recognised the existence of witches and supernatural agents, and enacted laws regarding them!*

But hermaphroditism, even to the extent it is said to take place in fishes, is a condition, as applied to man, opposed to all the existing states of social intercourse, and so deeply affecting all human institutions, that its very rare occurrence in society may be referred to an original law ordaining it to be so; the same which fixed a limited and fixed duration of existence to all living beings, determined that in the vertebral kingdom the sexes should be separate, and even when re-united in one individual, there should not arise therefrom a competency in the individual to render unnecessary the conjunction of the sexes. For very obvious reasons, the whole frame of human society hinges upon a complete disunion of the sexes.

Deviations from natural structures are liable to become hereditary, and thus experiments made on the lower animals might lead to singular results: but still I do not think so; for there is an obstinacy in nature's laws to adhere to certain forms of existence; to certain laws from which she will not, or cannot, deviate. The reasons assigned by Aristotle for the production of monsters are as false now as then: that great man peopled Africa with monsters, which he ascribed to the mixture of different species brought together at the thinly scattered springs of water partially irrigating that arid waste; but enterprise shews us that nothing monstrous exists in Africa, excepting, perhaps, human institutions;

* There are facts, moreover, in the economy of the higher organised animals, which oppose the notion of any vertebral animal being capable of exercising both sets of organs, even though possessing both. In those cases of hypospadias which occasionally occur in the ruminants, and of which there is a specimen on the table, the animal seems to have no real female propensities: hence the constant wetting of the wool each time the urine is discharged, because the animal being male does not feel the necessity of assuming the position of the female in discharging the urine, and hence it seems to dribble away, but in fact it does not do so. I do not think it exactly proved that any animal whatever is strictly hermaphroditical, in the sense assumed by the vulgar.

* In a very ancient Hindoo code it is forbidden to offer as sacrifices to Shivas, the blind, the crippled, the aged, the sick, the hermaphrodite, &c.

the works of nature which are found there being beautifully perfect.

The general influence of hermaproditism over the body is remarkable; but this subject has been exhausted by others. I have placed on the table what may be called a deformed male and female pelvis, as explanatory of the limits set to that influence by causes of which we are entirely ignorant; and thus sometimes the upper half of the body may be completely female, the lower half male, and the whole outline female, with male organs sufficiently developed and active. This influence undoubtedly extends to the intellectual organs, and to the form of the head.

Hermaphroditical appearances are extremely rare in birds, and they have never been observed in reptiles. The destruction of one set of organs—the female, in birds—gives a tendency to male habits; the bird assumes the male plumage. How far this is applicable to human structure has been supposed to be best exemplified in the case described by Mr. Pott. But there is something doubtful in all this; the descent of the ovaria through the rings shewed a leaning towards the male structure: Mr. Pott and his commentators do not seem to have thought of this. Mr. Pott's case is the first, or the only one, perhaps, recorded; his details are extremely imperfect, and, like nearly all his other pathological remarks, merely excite in us a desire to know more. M. Isidore Geoffroy remarks that “these organs (the ovaria) in their development, follow the course of the vasa deferentia in man; it is an anomaly resulting from a real excess of development, and very remarkable for the new proofs it furnishes in support of the analogy of the genital organs in the two sexes.” To me these expressions convey no meaning. The genital organs in the sexes have no analogies to each other, but are, on the contrary, diametrically opposite.

I have thus endeavoured to determine the original type of two great systems of organs in animal bodies, in the generative and respiratory; and in this inquiry I trust it has been made manifest that the philosophy of the animal organization, founded on an ideal analogy of organs, cannot be trusted. These doctrines have led anatomists to compare parts with each other, and draw resemblances in organs essentially and always distinct; in a

word, they have led to false conclusions. The opinions I have ventured to substitute for them are not contradicted, so far as I know, by any striking anatomical observation. The memoir which I trust to have the honour of submitting to the Society shortly, on the double type of the respiratory organs being at once pulmonary and branchial, together with the determination of the osseous apparatus connected with these organs, will put these doctrines to the test.

CASE OF ERGOTISM.

By JAMES B. THOMPSON, M.D.

(*For the Medical Gazette.*)

THIS disease, if disease it may be called, is often met with amongst the natives of the western coast of Africa. It was remarkably well marked in the following case:—

A lad of about eighteen years of age, servant to the brother of Governor Rankin, then residing at the Gambia. It was observed that whenever this boy was in the act of brushing the flies and mosquitos from his master, while at dinner, he dropped off into an apparently sound sleep, and remained fixed in his then position. He was often noticed to do the same when about to get any thing from off the side-board, or in opening a closet in the dining room. It was often amusing, indeed most laughable, to behold him during this period of somnolency. He was not unlike a person going about the house in his sleep. Indeed, there seems to be some analogy between this affliction and that of a confirmed somnambulist: but the former cases are more generally followed by serious, sometimes fatal consequences, after a period of years have elapsed. It would appear as if the circulation in the brain was much engaged; death, in such cases, mostly terminating in a form of asphyxia or apoplexy. I am not aware that autopsies have thrown any light as yet on the subject; nor do I imagine we are as yet in possession of the most judicious treatment for such anomalous cases.

CICERO.

ELECTIONS.

THERE is something very disheartening to the sincere lover of truth, in the conflicting statements that attend every subject of discussion and dispute. No sooner are the feelings enlisted in any cause than the power of accurately weighing evidence, of making due allowance for exaggeration or perversion, of liberally constructing doubtful motives, seems to forsake even the most philosophical. There really seems no escape from the mistakes of party but in seclusion and indifference. Yet this neutral course, seemingly so safe and easy, is by no means free from its dangers or its annoyances. Indifference to their interests is the least offence of which, in the eyes of each party, the philosopher is guilty; he is more likely to be suspected by each of positive opposition. Woe to the man who has not early imbibed a prejudice on one side or the other. He is liable to the same kind of rebukes as Sir Roger de Coverley met with, when a boy, in his inquiries for St. Anne's Lane. Parties ran high at the time, and the first man he inquired of asked him, peevishly, who made Anne a saint? and on his dropping the offensive prefix, the next called him "a crop-eared cur, and told him St. Anne was a saint before he was born, and would be one after he was hanged." It may even be doubted whether those who have the means of coming to a just decision on questions of public importance, have a very clear right to remain neuter; and society is not far out, perhaps, when it attributes neu-

trality to indolence or timidity; or to other causes less flattering than that of a conscientious and dignified reserve, which is warranted by a careful balancing of evidence, and a truly philosophical decision.

There is a kind of neutrality, too, not uncommon, very dangerous to him who adopts it, and very uncomfortable to his neighbours, that, namely, which will not stand the test of provocation, but which is liable, on some slight offence really or apparently personal, to be tempted into the lists which had been quitted, and to lend its aid, at an unexpected period of the contest, with manifest and gross unfairness. "The Pasha of many Tales" interrupts one told by a British sailor, we think, at the words "armed neutrality," and inquires the meaning of the term, which was new to him. He is drily told that the signification varies at different times, but that just now it means "a charge of bayonets."

Perhaps out of all the letters which reach the journalist on such a subject as a contested election, there is hardly one which those who best know the circumstances of the case can entirely approve. The warmth with which the effusion has been moulded has usually left on it some marks of distortion: deficient information, hasty construction, unwarrantable conclusions, characterize nearly all such productions; and although, if they were all printed, the well-informed might gather some more information from their compilation, the uninformed and the misinformed, who want most assistance, would but become more bewildered. A summing up, and an opinion given *ex cathedra*, may, however, be expected of the journalist, but an opinion so given is at once set down by those whom it does not entirely favour, as that of a partizan,—one more of the many that ought to be combated.

We may shew a man a column of figures, and tell him the bottom line contains their amount; he may believe us; but only those who have done the sum are quite convinced of its accuracy. Assuming, therefore, that we know exactly the rights of each part of the case, and could if we would give an unexceptionable verdict, let us lay aside as settled, the *matter*, and say a few words as to the *manner* of conducting disputes. The knights of old went about, we learn, as defenders of the right against the wrong, redressing grievances, and settling disputes, by the means then most in vogue for making men think alike; and a vast deal of good they did, no doubt; some capital verdicts they gave, some very just damages they enforced. But besides his general advocacy of the right and the true, each champion rode forth prepared to assert that his own mistress was the most beautiful and most virtuous in the world. This gave plentiful employment in the intervals of great undertakings, and hardly any two of these worthies could proceed together to or from the castle of some murderous giant, without a little private quarrel about the merits of their respective dames. Nine times out of ten an acquaintance began with a battle, and, after a sufficient banging, ended in a warm friendship. Each admired in the other the qualities which he had displayed in the combat, and they loved each other as those only love who have exchanged a beating in a worthy cause with a worthy opponent. But a foul stroke, an unfair advantage, a recourse to sorcery, or any other breach of the laws of honour and chivalry, earned for the recreant who practised it contempt and hatred. Now, as we have all our prejudices and prepossessions, for which we contend as keenly, though not so bloodily, as the knights-errant

did for their mistresses, and as life is passed in daily conflict for these prepossessions, and for our several interests, it is above all things important that we should take care, whichever way the battle may go, so to bear ourselves that we may gain and not lose friends in the contest. The smart manner and bold assertions of a zealous committee-man may gain a vote or votes, but do not pay in the end if they damage our reputation, or loosen a private friendship.

One word about committees. We have often wished, when religious parties ran high, that we could get opposing divines to change pulpits occasionally; and it would be a capital arrangement if the most zealous friend of the opposite party were retained in each committee room, to give his opinion on the various notions entertained and expedients adopted. The more fiery the character of this friendly enemy the better; and lest zeal should cool by hearing too much on the other side, he might be changed occasionally, and so kept at a useful temperature, with a proper glow of honest indignation on his countenance. The experiment is surely worth trying*.

DOCTORS' BILLS.

A good humoured letter was addressed to the Editor of the Times, the week before last, by one signing himself *Antibillions*, who complains that his friend "Phial" has for the last two years departed from his usual custom of specifying every pill, draught, mixture, &c. supplied to his family, and merely charged "for medicine and attendance, as per ledger — pounds, &c." *Antibillions* seems to be a solicitor, for he doubts whether his clients would be content with so compendious an account of the services he has rendered

* There is a plan very much applauded in committee-rooms, but which seems sadly opposed to morality, and even decency. It is called the "neutralizing promises, and consists, in fact, in inducing those who have *promised* their votes to one candidate, to *break their promise*.

for the various six-and-eight-pences which make the sum of his yearly bills, and is quite sure that no butcher, baker, or other tradesman, who should charge in a like manner, would ever be paid.

"A General Practitioner" answers this letter, and is rather angry with the lawyer for classing his old friend "Phial" with the butcher and baker, though the lawyer's own bill had been placed, by implication at least, in the same category. He dwells on the present liberal and expensive education of the general practitioner, and thinks, very properly, that people ought to pay for what the lawyer charges under a separate head, namely, advice and attendance.

But this clearly gives the lawyer the whole benefit of the argument. He does not grudge the amount of his medical bill, or dispute the correctness of his old friend's ledger, but he does wish to know what he has had, or might have had, for his money. The writers of two subsequent letters, "A Looker-on," and "Chirurgus," have between them stated the real remedy for the evil, which is just what common sense points out, namely, that charges should be made for attendance and advice, not for medicine; and that the times when such attendance and advice were given should be accurately specified. We strongly recommend "Old Phial" to adopt this plan; his visiting-book is of course as accurate as his ledger; and his visits may be posted side by side with his draughts; and we would engage that his old friend *Antibillious* would rather be reminded of having seen his cheerful face in the house on any given day, than of having had a black, white, or yellow draught sent him; especially as he very candidly owns to having doubts whether all the physic sent to his house was ever swallowed or not.

The writers of the two last letters both lament that the degrading practice of keeping open shops, and selling drugs, should be continued by medical men. There is no doubt this does the whole profession, but especially the general practitioner, much harm with the public. It confounds the real distinction between the educated prescriber and the mere vender of drugs; but the practice of charging for medicine at all, as a remuneration for at-

tendance, does perhaps still more damage, for it raises the importance and increases the profits of the mere druggist; and these very profits induce educated men to open these attractive retail shops, from which the public form their own notions and draw their own inferences, as to the functions, the habits, and the qualifications of "Doctors." We have before said, that we have no faith in public meetings to set these matters right. Let those who feel the evils of the present system, and especially the degradation which it causes, use their private influence and personal example, to promote a temperate and gradual reform.

LECTURE

ON

ABSCESS AND FISTULA CONNECTED WITH THE RECTUM,

Delivered in the Theatre of St. George's Hospital, January 3, 1844,

BY SIR B. C. BRODIE, BART.

GENTLEMEN,—I presume you are all aware that abscesses are very liable to form in the vicinity of the rectum, and that when they are formed they for the most part do not heal spontaneously. You are also aware that the parietes of the abscesses contract, become hard and callous, and that in this stage the disease receives the name of *fistula in ano*.

The disease is one of sufficiently common occurrence in hospital practice, but it is much more frequently met with in private practice. It is very distressing to the patient, and in every way of great interest to the surgeon.

The first questions that present themselves to us are, wherefore is it that these abscesses are particularly liable to form in this situation? and wherefore do not abscesses which are here formed heal spontaneously, like abscesses elsewhere in the cellular membrane? I was accustomed formerly to suppose that the healing of these abscesses was prevented chiefly by the constant action of the sphincter and levator ani muscles. Further consideration, however, and a more mature experience, have led me to believe that this opinion was incorrect. That the action of muscles in the neighbourhood may interfere with the healing of an abscess there can be no doubt; but that it should prevent the healing process altogether seems to be not sufficiently probable, and at any rate the formation of the abscess cannot be explained in this manner.

In order that we may arrive at the real origin of the abscess which forms in connection with the rectum, I must call your attention to what happens in other parts of intestinal canal. The mucous membrane, under a variety of circumstances, is liable to ulcerate. In patients who die of diseased liver, of phthisis pulmonalis, at the end of continued fever, and in several other cases, the mucous membrane of the bowels is found to be ulcerated. In the majority of cases the ulceration does not extend into the muscular tunic; but sometimes it does so, and not only to the muscular tunic, but also to the parts beyond that tunic, and then some of the contents of the intestine escape. If this happens where the bowel is covered by peritoneum, feculent matter may find its way into the peritoneal cavity. For instance, a little boy seven years of age had symptoms of mesenteric disease, at the conclusion of what was supposed to be a fever. When he seemed to be in a state of convalescence he was suddenly seized in the evening with a kind of fainting fit, during which his pulse could not be felt. After some time, under the influence of stimulants, he recovered from the fainting, but continued low and depressed. On the following day, however, another attack took place, from which he did not recover. On a *post-mortem* examination, I found that there was ulceration on the inner surface of the ileum, and that the mesenteric glands were diseased, as they are in scrofulous children. In one place the ulcer had by a small opening extended through both the muscular tunic and the peritoneum, and a small quantity of feculent matter had escaped into the abdominal cavity. Every one who has had much opportunity of seeing the progress of disease, has met with cases of this kind. But there are other cases, in which both the muscular and peritoneal coats ulcerate, and yet the contents of the intestines do not escape into the peritoneal cavity. Adhesions take place round the ulcerated spot, and the consequence is, that when the ulceration of the peritoneum is complete, the contents escape, not into the abdomen, but into the cellular membrane of the abdominal parietes. For example, a young man, 18 or 19 years of age, who had long been in ill health with disease of the lungs, besides being ill in other ways, was seized one evening, when he was supposed to be rather better, with violent pain in one side, which extended, with considerable tenderness, over the whole abdomen. Two physicians were called in, and they supposed that he laboured under peritoneal inflammation. The symptoms, indeed, were not exactly those which peritoneal inflammation commonly produces, but still they could not explain them so well on any other supposition. These

inflammatory symptoms subsided, and some time afterwards I was called in to see him, in consequence of a tumor having formed in the front of the belly. It was an abscess. I opened it, and there came out pus; but besides that there was a good deal of foreign matter, which I was satisfied must have come from the intestinal canal. After this, abscesses presented themselves in several other places, and the patient ultimately died. On examining the body, it was found that there were ulcers at the lower part of the ileum. One of these had extended through the muscular and the peritoneal tunics, but all around the ulcer the ileum had contracted adhesions to the abdominal parietes above the groin. Matter had escaped into the cellular membrane apparently between the layers of the abdominal muscles, and from thence had made its way forward to the part where the abscess was opened.

This patient, I have said, died; but death is not a matter of course under such circumstances. I was sent for to see a little boy who had been supposed to labour under mesenteric disease. When I saw him, there was an abscess near the navel discharging pus and feculent matter. Attention was paid to his general health; he was kept in a recumbent position, lying on his back (a most essential part of the treatment), and some very simple dressing applied to the wound. The boy ultimately recovered. He was, at any rate, alive two or three years afterwards. In a similar case a boy lived a considerable time afterwards; but after he was taken away from London I had no opportunity of knowing what happened to him.

The part of the intestine in which ulceration is most likely to take place is the lower part of the ileum. It not unfrequently occurs, however, in the cæcum. The abscesses of which you hear in the right iliac region generally have their origin in the cæcum. A young man jumped from a coach, and felt, as he said, something give way in the right groin. He came to London with a tumor there, and, thinking that there was a deep-seated gland suppurating, I advised him to go home, to keep quiet, and apply a poultice. About a month had elapsed from the time when he jumped from the coach, when he sent to me to say that the abscess had burst. It was discharging pus of a very offensive odour, and it was plain that there were feces mixed with it. He had no bad symptoms for two or three days. I did not tell him the exact nature of the case, for he was a very nervous man, and I thought it would alarm him. Two or three days afterwards, however, having taken a draught of decoction of bark, to his great horror he observed that the medicine came out at the groin. This frightened him out of his wits; and from

that period his nervous system began to give way. He fell into a state of great nervous excitement, and died ten days after the abscess had burst. On examining the body after death, I found an ulcerated opening of the cæcum at the posterior part, through which the feces had escaped into the cellular membrane, and formed the abscess which had presented itself in the groin. There was a woman in this hospital with an abscess in the groin which was supposed to be connected with dead bone (as indeed is the case with the great majority of chronic abscesses). Perhaps sufficient attention was not paid to the quality of the discharge, but one day, the patient, on taking off the poultice, found in it an intestinal worm (a lumbricus). She ultimately died, and on examining the body we found an ulcerated opening at the posterior part of the cæcum, through which the lumbricus had made its way; and it was evident that this ulceration had been the origin of this abscess. I mention these cases, though they are by no means singular, because the recital of particular cases will often impress an important fact on the mind better than a mere general observation.

Now I believe that this is the way in which abscesses of the rectum are always formed; that originally there is an ulcer of the mucous membrane of the bowel extending through the muscular tunic into the cellular membrane external to it; and I will state my reasons for that opinion. It is a matter of some interest as a question in pathology, but it is of great importance, as I shall shew presently, in connexion with surgical practice.

First, there is the analogy of such cases as I have already mentioned, in which abscesses are formed external to the bowel from ulceration of the mucous membrane. It is admitted by every one that in the greater number of cases of fistula in ano there are two openings, one communicating with the interior of the bowel, and the other externally. But for my own part, I have no doubt that the inner opening always exists. I scarcely ever fail to find it in the living person when I look for it in the proper place, and seek it carefully; and when I have had the opportunity of examining the appearances connected with fistula in ano in the dead body, I am not aware that I have ever failed to discover the inner opening in a single instance. And this offers a very reasonable explanation of the formation of these abscesses, and it is almost impossible, on any other hypothesis, to understand why suppuration should take place in the cellular membrane in the neighbourhood of the rectum more than in the cellular membrane elsewhere. The pus contained in an abscess near the rectum scarcely ever presents a healthy appearance; it is always dirty-

coloured, offensive to the smell, and sometimes highly so. Occasionally you find feculent matter in it quite distinct. There is no reason why an abscess, simply because it is formed in the cellular membrane, should smell of sulphuretted hydrogen, but there is a good reason why that should be the case if it be connected with the rectum, and with the infiltration of its contents into the cellular membrane.

It is easy to understand, on this ground, why these abscesses do not heal. A small quantity of mucus from the gut, or of feculent matter issuing into the cavity of the abscess, is sufficient to prevent the healing process from going on.

I have more than once, in the living person, been able to trace the whole progress of the formation of one of these abscesses. For example, I was sent for to a lady who complained of some irritation about the rectum. On examining the bowel, I found that there was an ulcer at the posterior part, and I ordered her to take Ward's paste (*confectio piperis nigri*), or cubebæ pepper; I cannot recollect which. About a month afterwards she again sent for me; there was an abscess, which I opened, and the probe passed into the outer opening at once entered the gut, through the ulcer, about which I had been originally consulted.

The primary opening of the abscess is generally very small indeed. But sometimes it is of considerable size; perhaps large enough to admit the end of the little finger. The inner orifice is, I believe, invariably situated immediately above the sphincter muscle, just at that part where the feces are lodged before they are finally expelled.

I conclude that the most frequent cause of abscesses of this kind is the lodgment of hard feces in the bowels. By the straining which is requisite to expel them the mucous membrane is torn, or abraded in one part, and then the continued contact of the feces causes ulceration. At a subsequent period straining again takes place, the muscular tunic gives way, and a little of the feces escapes into the cellular texture. Foreign bodies impacted in the rectum are sometimes the cause of abscess. I was called to a gentleman who complained of great irritation about the rectum. I concluded that he had internal piles, but on the following day he complained still more, and on examining the rectum, I found a hard substance sticking in the mucous membrane. It proved to be a piece of apple core which he had swallowed the day before. If this had not been extracted, it would have occasioned an ulcer, some of the feces would have passed through the opening, and the probability is that the apple core would have been found in the cavity of the abscess. I was sent for to see another gentleman who was ex-

ceedingly ill with a large abscess in the front of the anus. He had a brown or rather a black tongue, attended with severe typhoid symptoms. I opened the abscess freely, let out a quantity of putrid offensive matter, and on introducing my finger into the abscess I found a long fish bone lying across, with one end stuck in the gut and the other in the abscess. The fish bone had traversed the rest of the intestinal canal easily enough, but when it met with the obstruction caused by the sphincter muscle it penetrated the tunics of the rectum, and a little of the fæces escaping by its side formed a putrid abscess. Persons who are otherwise in certain states of ill health are especially liable to abscess and fistula of the rectum—those, for example, who labour under disease of the liver or disease of the lungs. The reason is, they are especially subject to ulceration of the mucous membrane. In these cases I imagine that the ulcer begins in the mucous glandules.

The first formation of abscess about the rectum is not in general attended with very urgent symptoms. The patient has a sense of bearing down, fulness, and weight. Thinking that he has got piles, he puts his hand by the side of the anus, and finds a little hardness. By and bye this hardness increases, the parts become tender, there is pain in passing the evacuations, and perhaps some difficulty in doing it. As the abscess advances the pain becomes greater; at last it bursts, and a quantity of matter is discharged, which is almost invariably offensive, dark-coloured, and putrid. Occasionally, however, the disease is so insidious in its formation that the patient knows nothing about it till the abscess has given way. A physician in large practice in London, more than twenty years ago, became very ill, languid, and almost unfit to discharge his professional duties. He was under the necessity of going home in the middle of the day, in consequence of headache and an incapability of exertion, and lie down for an hour, before he could finish seeing his patients. One afternoon, having sent away his carriage, and intending to walk home, he felt something give way and burst into his small-clothes. It was a putrid abscess, which had formed near the anus, and it ended in a fistula, for which he went through an operation, and got well.

During the formation of these abscesses there is sometimes little or no constitutional disturbance, while in other cases there is a great deal of it. I believe that the constitutional disturbance depends chiefly on the quality of the pus, and that again on the size of the opening. If there be an opening of such a size as will allow a considerable quantity of feculent matter to escape, the pus is of a very putrid quality, and the more

putrid the pus the more offensive it is to the smell, and the more poisonous to the patient's system. The sulphuretted hydrogen in which the pus abounds, sufficiently explains its poisonous quality. Very urgent symptoms indeed does such a collection of putrid matter sometimes produce. I was called in to see an elderly gentleman in the neighbourhood of London, with the late Dr. Blick, of Walthamstow. The patient I will not say was in *articulo mortis*, but he looked as if he had not long to live; I should hardly have supposed 24 hours. On inquiry into the history of the case, I learned that he had had a fistula by the side of the rectum for many years. He was afraid of an operation, and had suffered the disease to go on. The external orifice occasionally closed for a time, but in a few days it opened again, and the matter escaped. Some two or three months before the time at which I was called in to see him, the outer orifice of the fistula closed, and from that time there had been no discharge. At first he experienced no inconvenience from it, but by and bye there was a sense of pressure, and bearing-down of the rectum; his health became disturbed. At last typhoid symptoms came on, and, as I have said, he appeared to be almost dying. I examined the parts externally, and I perceived that the external orifice of the fistula was firmly cicatrised. I introduced my finger into the gut, and above the sphincter muscle I could feel a tumor on one side, evidently an immense collection of matter. With the fore-finger of one hand in the rectum I introduced a lancet with the other hand, and ran it up to the point where the matter was collected. Not only the shoulders of the lancet, but the whole blade, was buried before matter escaped, and then there came away a little of a putrid odour. I dilated the opening with a probe-pointed bistoury, and then there escaped a pint of matter so putrid and offensive that the whole house was poisoned by it. The smell could hardly have been worse if a nightman had emptied his cart into one of the rooms. The patient was better directly. Fortunately, although there was a very free incision, there was no bleeding, and he recovered without a bad symptom. This took place many years ago, and the gentleman died lately of another complaint.

I have told you that the inner orifice of the abscess is always just above the sphincter muscle. It may be that the abscess terminates just at this spot, but in the greater number of cases it extends higher up, sometimes one or two inches; nay, I have known a probe to pass four or five inches up the pelvis, apparently into a large cavity on the side of the rectum. These are cases of some interest, of which I shall have to speak to you again.

The external orifice of the abscess is generally in the skin, at a little distance from the anus. Sometimes it seems to pass through the substance of the sphincter muscle, and at other times to open externally to it. The abscess may burrow, and it may then be two or three inches away from the anus, or even farther still. In some cases there is no external opening at all, and that may happen in two ways. I saw a gentleman who had an ulcer of the rectum; it was at the posterior part, and as broad as a four-penny piece. I saw him some time afterwards, and there was a considerable discharge from the rectum, but no external opening. I introduced my finger into the rectum, and found that this broad ulcer had made a large cavity, in which matter was lodged, behind the rectum. There was no external opening, because the sinus was so large that the matter, as fast as it was formed, found its way out by the gut, and therefore did not collect in any large quantity. In other cases, where there is no external opening, there are two internal ones, and they are formed in the following manner: first, a small opening through which the feces and mucus were originally infiltrated into the cellular membrane, and then another larger one, formed by the abscess bursting into the gut afterwards. When you examine a patient in this condition, you find a discharge of pus from the inside of the rectum, and none from the parts on the outside. This is commonly termed a *blind fistula*. The discharge in this case is generally not quite constant, in consequence of the opening made by the bursting of the abscess into the rectum being at times partially closed. At these periods the matter collects by the side of the bowel, and you may feel it near the anus through the skin. At other times the orifice allows the matter to escape into the rectum, and then the external tumor disappears.

In some instances there is a simple abscess, and a simple sinus, but in others you find the disease very complicated. The matter does not easily get to the surface, and it burrows in different directions; there is a sinus in this direction, and a sinus in that; and they sometimes extend to the middle of the nates, or even to the opposite side of the rectum. In these cases where there are several sinuses, and where the disease is complicated from the burrowing of the matter, it will sometimes happen that there are two internal openings, but in the greater number of cases there is only one, which is connected directly with one sinus and indirectly with the others. This is a matter of great consequence to bear in mind as connected with surgical treatment. Where there are several sinuses each burrowing in a

different direction, the patient is always subjected to some degree of inconvenience. The matter lodges sometimes in one place and sometimes in another, and wherever it lodges it occasions pain. There is, perhaps, an attack of shivering, and then the matter escapes; it afterwards lodges in another place, and produces another attack of shivering, and thus, in these complicated cases, the patient is continually tormented, both locally and constitutionally.

I now come to the consideration of the treatment of these cases. Why is it that the abscess does not heal? I dare say it may arise partly from what I formerly considered to be the cause; namely, that it is an unfavourable locality for healing on account of the muscular fibres of the part being always in motion. The levator ani muscle and the sphincter are constantly drawing the parts asunder, and consequently do not allow of their contraction. That, however, as I have already observed, is not a sufficient explanation. There is an internal opening to the abscess, and every now and then a small portion of feces, or of mucus, becomes infiltrated into it, and the same cause which produced the abscess in the first instance prevents the healing afterwards. If the inner orifice could be closed, the case would go on well, and this sometimes, though rarely, happens. I saw a patient who had an abscess by the side of the rectum, and to whom I recommended an operation, but for some reason or other he put it off. He went about for a considerable time with the abscess open, but at last I saw him again with the abscess healed, and it had been closed so long, and the parts seemed so sound, that I have no doubt it had healed soundly. I conclude that the inner orifice had closed spontaneously, and the escape of the feculent matter being prevented, there was nothing to prevent the abscess from contracting and healing like an abscess situated elsewhere. There is a medicine which is now in the Pharmacopœia under the name of *confectio piperis nigri*, which was originally sold as a quack medicine called *Ward's paste*. It is composed chiefly of black pepper and elecampane, and it had a reputation for curing fistula. I believe that it sometimes does produce this effect, and undoubtedly it is very useful in cases of piles, and of ulcers of the rectum unconnected with fistula. The *modus operandi* is probably this; the black pepper mixes with the feces, and passing down the canal it becomes a local application and a stimulant to the mucous membrane. In this way it is often beneficial to persons that suffer from disease of the mucous membrane after dysentery. In a case of *fistula* we may suppose that the black pepper stimulates

the ulcerated opening of the rectum so as to cause it to contract and cicatrise, and this being done there is no reason why the abscess should not heal also.

But you cannot place dependence on such a mode of treatment as this; for where it may cure once it fails a great number of times. The disease, however, may in general be cured by a very simple operation. In explaining the objects and the nature of the operation, I will first take the simplest case, one in which there is a fistula just by the side of the sphincter muscle, and only a single sinus. The first thing to be done is to find the inner opening. I do not say that you will always succeed in finding it, and certainly not always on the first trial; but you will rarely fail to find it at last if you look for it in the right place. I used frequently to fail formerly, and for a very sufficient reason—I did not know where the opening was to be found. Remember that it is situated, not at the upper extremity of the *fistula*, but immediately above the sphincter muscle. Then I should observe, that the common probe, being quite round, turns round in the hand, and is not a convenient instrument for the examination. For this operation I use the probes which I now shew you, and which are made by Philp and Whicker, in St. James's Street. There is a flat handle, which affords a perfect command of the instrument. From the handle it gradually becomes smaller towards the other extremity, which is made like that of a common probe. Then there is a groove to within about an inch of the smaller extremity, so that it is a probe and a director at the same time.

Now, to find the inner opening, let the patient lean over a table where there is a good light, and having an assistant to hold the nates asunder. You then introduce the fore-finger of one hand into the rectum, bearing in mind that the opening will be found close to the sphincter muscle. Generally speaking you will feel some little irregularity where it is situated. You are then to introduce this instrument (which, as I have stated, is both a director and a probe) into the external opening, and with the assistance of the finger in the rectum, taking care to use no force, you feel for the inner opening first in one direction, then in another, until at last the end of the probe slips into it. This part of the operation must be performed with a very light hand; with which precaution a little practice will enable you, in the very great majority of cases, to find the inner opening easily enough. You will know when the probe has gone through the opening by its coming in contact with the finger. If you do not find the opening on the first day, defer the operation until a subsequent day, when you may perhaps suc-

ceed better. It is well worth your patient's while to submit to this delay, the operation being very simple when you can find the opening, and the result being very uncertain when you cannot. The inner opening having been detected, and the probe being in contact with your finger, you bend the round extremity of it, and bring it out at the anus. The part towards the handle is then seen projecting from the outer opening, and the other part from the anus. The whole of the soft parts which lie between the two openings are now to be divided; and for this purpose I find a pair of curved knife-edged scissors to answer better than a bistoury, which stretches and tears the parts before it cuts them. I may observe, that the incision required is for the most part very trifling—not more than an inch or an inch and a half in length—yet, in making it, a great part of the sphincter muscle is generally divided.

Having completed the operation, all you have to do is to prevent the cut edges growing together. You have converted the fistula into an open sore: some of the feces may go into it, but they do not lie and lodge there, and there is nothing to prevent the parts from granulating and healing from the bottom. All that you have to do is to dress them lightly between the cut edges, so as to prevent the latter from becoming united. As soon as these are skinned over, you may leave off the dressing, and the rest of the healing process goes on without your aid.

But suppose that the fistula has been burrowing in the direction upwards, and you find that it extends high up by the side of the rectum, what course must you then pursue? Formerly I imagined that it was necessary to lay open the whole of such a sinus into the rectum; but it is a frightful thing to do so. You do not know what large vessels you may divide. It is seldom that there is much bleeding by dividing merely the parts between the inner and the outer opening; or even if there should be, the pressure of the finger and a bit of lint stops it directly. But I remember a case where I divided a fistula some way up by the side of the gut, and bleeding ensued so that the whole of the colon was filled with blood. It is true that the hæmorrhage stopped, and the patient got well; but still he might have died. The bleeding, in this instance, went on insidiously; but if you really know that it is taking place, you do not know how to stop it. The bleeding vessels are so situated that you cannot secure them by the ligature; neither can you make pressure on them in any efficient manner. I am satisfied now, and have long been so, that a division of the whole length of a sinus, where it extends above the inner orifice, is quite unnecessary. Upwards of twenty years ago, when I was

first getting into practice, I had a patient with fistula, which I divided, or at any rate thought I had done so; but one day, when examining the parts with a probe, I found a continuation of the sinus running up several inches by the side of the gut. It appeared as though one side of the rectum had been completely dissected from the neighbouring parts; but there was a good opening for the discharge of matter at the lower part, where I had divided the lower portion of the fistula. I doubted what I ought to do in such a case, and I called in the late Mr. Cline. I said to him, "I really am afraid that, if I were to divide the whole of this long sinus, the patient might die of bleeding." He replied, "you are quite right; and more than that, I do not think it is necessary. I would leave it alone." I acted on this suggestion, and the patient got well without any trouble. I have since seen other cases of the same kind, which I have treated in the same manner, and with the same success.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

Tuesday, January 9th, 1844.

THE PRESIDENT IN THE CHAIR.

Case of the Removal of a Diseased Ovary, terminating fatally on the seventh day after the operation. By J. M. GREENHOW, Esq., Surgeon to the Newcastle Infirmary and Eye Infirmary. [Communicated by Sir B. C. BRODIE, Bart.]

THE patient was aged 29 years, and married. For four years she had suffered from frequent discharges of blood from the uterus. Eighteen months ago—that is, six months after her marriage—the swelling in the abdomen commenced at the pubic region, and rapidly increased till it attained a large size; her strength all the while declining from the constant uterine discharge. The abdomen was tapped, and only a little blood escaped; but afterwards nearly a quart of dark-coloured fluid was discharged daily from the wound for about a fortnight. Before the operation of removing the tumor, which was performed September 3d, the abdomen was about as large as at the full period of uterogestation; there was fluctuation in one or two parts, but generally the tumor was firm, and felt as if divided into separate masses. The incision reached from a little below the ensiform cartilage to near the pubis. Several adhesions existed at different parts, the principal one being to the omentum, which was spread over the upper part of the right side of the tumor. These adhesions were

divided with the bistoury, and then the tumor was raised, with some effort, owing to its great size and weight, from its situation. Double ligatures were passed through its pedicle, and firmly tied; and this part being divided near the tumor, it was liberated from its attachments, and removed. Two arteries bled freely, one in the divided omentum, and the other in the pedicle; upon these being secured, the wound was brought together by sutures and adhesive plaster, and a bandage applied.

The operation was well borne by the patient, although she vomited several times towards the end. The quantity of blood lost did not exceed six ounces. The symptoms which followed were chiefly great retching and vomiting, constipation of the bowels, quick pulse, tenderness and distension of the abdomen; and she died on the morning of the seventh day. On the post-mortem examination, the folds of the intestines and the omentum were found glued together by recently effused lymph; there was inflammatory redness, with points of ulceration near the pyloric orifice of the stomach. The uterus was healthy, but its cavity was lined with a vascular membrane like the decidua. The morbid growth had been attached to the left broad ligament. On examining the tumor, it was found to weigh twelve pounds seven ounces, and to be more than two feet in circumference. Its surface was smooth, and of a pale colour, resembling that of the skin. With the exception of a few cysts containing a yellow fluid, the general mass was composed of a dense and vascular cellular structure, with a number of small cells or cysts pervading its substance. The author concluded by making some remarks on the case; he directed attention particularly to the disease found in the stomach, which he considered had an important influence in leading to the fatal termination; and thought, on the whole, that the result of the case did not offer a strong argument against resorting to a similar operation in such cases.

Case of Extirpation of an Ovarian Cyst.

By BRANSEY B. COOPER, F.R.S., Surgeon to Guy's Hospital.

The patient was aged 32, and married for four years, without having children. She had suffered at different periods from dysmenorrhœa and leucorrhœa. Five years before her admission her abdomen became greatly enlarged, and, having consulted the author, he considered the case to be one of ovarian tumor, and proposed to draw off the fluid from the cyst, and then remove the cyst by a small opening in the abdomen. But this plan was not carried into effect. She was afterwards tapped on two different occasions, when about three gallons of straw-

coloured fluid were discharged each time. When she applied at the hospital, earnestly soliciting to have the operation of removing the tumor performed, her abdomen measured about three feet and a half in circumference. Mr. Cooper resolved to perform the major operation. An incision was therefore made through the abdominal parietes, from the ensiform cartilage to the pubis. A few adhesions to the tumor were met with near the point where the trocar had entered in tapping; these having been divided, the cyst was dislodged and brought out through the wound, when the pedicle connected with the right ovary came into view. A double ligature was passed through the pedicle, and both threads having been tied, the pedicle was divided between the cyst and the ligatures. The left ovary was examined, and found to be healthy. The wound was then brought together by sutures and strapping, and a roller applied round the abdomen. There were some attempts to vomit during the application of the ligatures, but otherwise the patient bore the operation well. A minute record was given of the daily condition of the patient subsequent to the operation; but it is sufficient to say that distinct symptoms of peritonitis soon appeared, and the patient died on the seventh day, without any indication of the system rallying.

On the post-mortem examination, lymph was found effused extensively over the abdominal parietes and viscera, uniting them in many places together. A small piece of omentum was enclosed in the ligature applied to the pedicle. The uterus was large, tumid, and of a dark colour; and a soft fungous tubercle, pronounced, after microscopical examination, to be malignant in its structure, was found on its fundus. The cyst which was removed was of an oval form, and at its superior and anterior part there was a collection of compound cells. Its weight was 32 pounds.

The author concluded by making some general observations on the operation. He drew attention to the peculiar kind of inflammation which followed, and was inclined to think that it was excited more by the presence of the ligature applied to the pedicle, and left in the wound, than to the extensive incision. He also noticed the fact of a tumor of fungoid structure having been found growing from the substance of the uterus, and thought that this was interesting as illustrating the views of those pathologists who believe ovarian tumors, consisting of cysts, to be malignant in their nature, and as bearing on the question of the propriety of removing such tumors by operation.

LETTERS
ON THE
NERVOUS SYSTEM OF THE
GRAVID UTERUS,

ADDRESSED BY

MESSRS. PAGET, LAWRENCE, STANLEY,
SKEY, SIR BENJAMIN BRODIE, AND
DR. GULLIVER, TO DR. ROBERT LEE,
AFTER EXAMINING HIS DISSECTIONS.

To the Editor of the Medical Gazette.

SIR,

MAY I request of you the favour to print in your journal the following letters, which have been sent to me by different eminent anatomists, who have recently examined my dissections of the nerves of the gravid uterus.

I remain, sir,

Your obedient servant,

ROBERT LEE.

4, Saville Row, Jan. 15th, 1844.

“St. Bartholomew's Hospital,
“December 19, 1843.

“My dear Sir,—After the minute examination of your preparations of the nervous system of the gravid uterus which you permitted me to make, I examined your descriptions and Mr. Perry's delineations of them. Both appear to me remarkable for their accuracy.

“With regard to any doubt whether the structures which you have dissected be, as you have described them, nerves and nervous ganglia, it is chiefly by these following facts that I feel convinced of the truth of your account:—

“1. That there is a visible and orderly continuity between the well-known hypogastric and sacral nerves and the most minute and remote of the nervous cords which you have displayed. 2. That these cords, like those of larger size, have such an appearance of being nerves, as could not, I am sure, be imitated by dissections of any other known structure. 3. That the ganglia which you have found are like those of other parts of the sympathetic system, and have distinct nervous cords passing to and from them. 4. That many of the minutest, as well as of the larger, nerves are evidently associated with blood-vessels. 5. That the nervous system displayed is such an one as the pregnant uterus, from its known structure and functions, might be expected to possess.

“I think that your statements are proved by all the evidence to which it is possible, in the present condition of science, to attain; and I beg to add my congratulations to those which you have already received, on your having, by a truly admirable perseverance and dexterity, made one of the most

important anatomical discoveries of this century.—Believe me, my dear sir,

“Very truly yours,

“JAMES PAGET.

“*Dr. R. Lee.*”

“Whitehall Place, Dec. 28th, 1843.

“My dear Sir,—I have carefully examined your dissections of the nerves of the gravid uterus on various occasions; and I continue to believe, as I did in the first instance, that the structures you have succeeded in displaying are ganglia and nerves; while I am satisfied that your figures and descriptions are perfectly correct. The extraordinary and interesting spectacle you have set before us is so entirely novel, that some hesitation might very probably be felt in arriving at a decided opinion on the subject; yet this augmented size of nerves and ganglia is only analogous to the increased development of blood-vessels in the gravid uterus, with which we have been long familiar: probably a corresponding change might be found in the absorbing system, if it were submitted to the same kind of patient investigation which you have bestowed on the nerves.

“The considerations which have led me to form the conclusions above mentioned are exactly the same as those so clearly stated by my colleague Mr. Paget; I have, therefore, only to add that I entirely agree with what he has written to you on the subject; remaining, my dear sir, yours very faithfully,

“WILLIAM LAWRENCE.

“*Dr. R. Lee.*”

“Brook Street, Jan. 8th.

“My dear Sir,—In reply to your question with what impression I came from the examination of your dissections of the gravid uterus, I can have no hesitation in stating my opinion to be that your dissections do satisfactorily display the uterine nerves and their ganglia. Looking to the arrangement, connections, and relations with the blood-vessels, which the filaments and intumescences present, I cannot think otherwise of them than that they are the uterine nerves and ganglia.—Believe me to be, my dear sir,

“Yours sincerely,

“EDWARD STANLEY.

“*Dr. R. Lee.*”

“Grosvenor Street, Jan. 6th, 1844.

“My dear Sir,—I have much pleasure in complying with your request that I would state the result of my impressions on viewing your dissections of the impregnated uterus.

“I see no reason to doubt the correctness of your views, viz. that the immense network which you have so industriously investigated on the surface of the uterus is composed of true nerves and nervous ganglia. To my judgment they present all the visible

characters of nerves, and appear to be in direct communication with the pelvic branches of the sympathetic.—I am, my dear sir, very truly yours,

“F. C. SKEY.

“*To Dr Robert Lee.*”

“11, Saville Row, Dec. 29, 1843.

“My dear Sir,—I have carefully inspected your preparations exhibiting the nerves of the gravid uterus, and I can find no reason to doubt the correctness of the statements which you have published in the *Philosophical Transactions*.—Yours truly,

“B. C. BRODIE.

“*Dr. R. Lee.*”

“Hyde Park Barracks, Jan. 12th, 1844.

“My dear Sir,—I have read your papers in the *Philosophical Transactions*, on the ganglia, and on the other nervous structures of the uterus, and carefully examined the preparations which you exhibit as vouchers for the facts you have announced.

“Your descriptions and plates appear to me to be executed with remarkable fidelity.

“I cannot doubt but that the structures which you have shown by dissection are really nerves and nervous ganglia, because their fibres are clearly shown to be continuous with the sympathetic and with the sacral nerves, and because I do not believe that any ingenuity in the art of dissection could show such a regular continuity between the nerves and fibres of elastic tissue, or that this tissue could be made to imitate the nerves and nervous ganglia displayed in your preparations.—I am, my dear sir,

“Very sincerely yours,

“GEORGE GULLIVER.

“*Dr. Robert Lee.*”

COLLEGE OF SURGEONS.

To the Editor of the Medical Gazette.

SIR,

I SHOULD be averse from obtruding upon your readers anything which had merely reference to myself; but as much has been said respecting the various provisions of the new charter of the College of Surgeons; and having during a series of years transmitted to the *GAZETTE* information upon points of practice which I thought likely to be useful, I may, perhaps, be permitted to avail myself of its medium to remark upon the omission of my name from the list of Fellows, which I conceive (I hope without any undue self-appreciation) to be an instance of unfairness in the estimation of claims, being a member of fifteen years' standing, known in the profession, the author of one of the Jacksonian prize essays (On the Compar-

tive Advantages of Lithotomy and Lithotrixy), and of other works, on account of which most of the principal continental medical societies have paid me the compliment of conferring upon me their honorary diploma.

As far as I am individually concerned, the insertion or omission of my name would be to me a circumstance of little moment, and, in fact, I did not think about the matter, until my attention was accidentally directed to it on my arrival in town a few weeks ago, when I was recommended to submit my name to the consideration of the Council. Having done this, and afterwards perceiving in the list the names of several gentlemen some years my juniors, unconnected with any public institution, and who have not, as far as I am aware, any superior claim, I cannot but consider that many others must likewise have just grounds of complaining that, in many instances, a degree of partiality has been exercised, not in accordance with justice, or with the views of those by whom the power of selection was conferred.

I am, sir,

Your obedient servant,

EDWIN LEE.

Chester Street, Jan. 13, 1844.

TAUNTON AND SOMERSET HOSPITAL.

To the Editor of the Medical Gazette.

SIR,

I BEG to state for the special information of your correspondent, Dr. J. B. Badeley, of Chelmsford, that sixteen* fully qualified gentlemen have announced themselves as candidates for the office of House-Surgeon and Apothecary to the Taunton and Somerset Hospital, agreeably to the advertisement which has twice appeared on the "fly-leaf" of your valuable journal, and that the greater number of them sent in their applications, and testimonials of qualification, *prior* to the *second*† appearance of this said advertisement. Now, whether these gentlemen have been seduced into this act, by which, according to Dr. Badeley, they "will disgrace themselves and their profession," by the distant prospect of the "munificent salary," or whether they have been actuated thereto by some other wiser and more generous motive, I shall leave them to fight out with

the Doctor; but this much I may say, were Dr. Badeley as well acquainted with the real state of our much-overstocked profession as he appears to be with the "terms and wages of a servant out of livery," I am quite sure he would cease to express himself so severely with respect to an appointment, which is *at least some thing better* than his letter of the 9th ultimo would make it appear. The terms of the appointment are, salary £50 per annum, with board at the matron's table, and washing and lodging in the house." Or in other words, board and lodging (consisting of two private furnished apartments,) and all other necessities free of expense, with the addition of a clear salary of £50 per annum.

Now, Sir, it appears to me, that such an appointment may in all fairness be set down as equivalent to an ordinary income of at least £130 a year, and calculated to make the holder of it better off in a pecuniary point of view, and far more independent, than the great bulk of the hardly-worked and ill-paid juniors of our profession, or the half-pay veterans of the Army and Navy. Moreover, I would suggest to your correspondent, whether he does not think it possible that to most young men who have just completed their medical studies, the holding, for a few years, such an appointment as I have described—and such I will maintain the house-surgeoncy of the Taunton and Somerset Hospital to be, with the constant opportunity it must afford for collecting additional observations, and acquiring experience and confidence in the treatment of disease, would not prove a far wiser and more advantageous introduction to private practice than the usually-resorted-to office of assistant to some general practitioner, a district in a Poor-Law Union, or a surgeoncy to some vessel bound for India or Australia.

So much with respect to the applicants: and now a word or two with reference to the Governors of our hospital, against whom the wrath of Dr. Badeley seems, after all, to have been chiefly directed. As one, then, of the committee upon whom the duty of arranging the terms of the house-surgeoncy devolved, I beg to say that the sum of £50 was not fixed upon at random, nor in haste, but after a careful comparison of the number of beds with the amount of salary paid in thirty or forty provincial hospitals, when it was found that about a guinea per bed was the average rate of payment to the resident officer (for some hospitals, "*Heu miserabile dictu*," do not afford even £50 a year?); while with us the salary is of a higher rate, as may be seen by reference to the advertisement. But I would, in conclusion, assure Dr. Badeley that the sum of £50 was not determined upon from a desire to

* One of them is a highly intelligent graduate in medicine of the University of Edinburgh, in addition to his other qualifications.

† This advertisement appeared a second time in consequence of the Secretary having been originally instructed, viz. at the General Board, held on the 25th October, 1843, to insert it twice in each of the Medical Journals, and the Times newspaper, which order was never rescinded.

adhere rigidly to the spirit of any such averages merely, or in indifference to the feelings and labours of the future resident officer, but was taken as a *just* rate of payment—just as far as the average rate of such payment is considered, and just with reference to the limited funds of the hospital. The Governors, professional and non-professional, would have infinitely preferred giving a salary of £100 to one of £50: but the fact is, Sir, we humble folks in Somersetshire have a great respect for a certain homely saw, which declares “honesty to be the best policy,” and therefore we like to make our *honesty* keep pace with our *munificence*, believing it wiser and better to be *FIRST just*, and *THEN generous*.

I have the honour to be, sir,

Your obedient servant,

CHARLES HAYES HIGGINS,

Surgeon to the Taunton and
Somerset Hospital.

Taunton, Jan. 8, 1844.

To the Editor of the Medical Gazette.

Sir,

DR. BADELEY's letter to you will be best answered by the fact, that not less than fifteen qualified candidates have applied for the office of house-surgeon to this hospital, many of whom possess the highest possible testimonials both professional and personal, and several of whom have actively and laboriously canvassed the governors for the appointment during some weeks past.

The hospital is not opulent, and the governors are not able to do as they would wish to do in fixing for the present the salary of this important office. But, in seeking the appointment, respectable members of the profession doubtless have an eye to the opportunities of study and practice which it will afford, as well as to the maintenance which it offers.—I am, sir,

Your obedient servant,

WILLIAM PRICHARD, *Sec.*

Taunton, Jan. 8, 1844.

CAUTION RESPECTING THE QUALITY OF SURGICAL INSTRUMENTS.

To the Editor of the Medical Gazette.

Sir,

Now that the utility of Lallemand's operation of cauterising the prostatic portion of the urethra is generally acknowledged, and the correlative experience of British surgeons is likely to render it one of frequent application, I beg to submit to your readers a caution with regard to the instruments they employ.

Three or four years ago, I had occasion to adopt this practice in a case in which it answered my most sanguine expectations. While projecting the stylet, some drops of fluid flowed from the end of the catheter, which stained my fingers of the usual dark colour of Nit. Argent. Within a quarter of an hour I cleaned the instrument thoroughly, and laid it aside. About a year thereafter, I had occasion to employ it again. While examining the stylet previous to use, I found that the temporary application of the nitrate of silver had rendered it almost as fragile as the pith of a rush; it broke, on the application of the slightest force, into fragments of an inch in length. Had this occurred while the *porte caustique* was in the prostatic portion of the urethra, I leave your readers to imagine the consequences. The instrument was the production of a respectable maker, who, unfortunately, like too many who assume the name of “surgical,” was utterly ignorant of the science to which he ministered. He no doubt thought that he had honourably fulfilled his bargain by making the *ends* of the stylet of pure silver; the intermediate portion was of most villainous *German*.—I remain, sir,

Your obedient servant,

M.D.

LONDON AND PROVINCIAL HOSPITALS.

To the Editor of the Medical Gazette.

Sir,

A PARAGRAPH has appeared in most of the London papers (in the Morning Post and Times of Saturday last) headed “Town and Country Practice,” which I enclose for your insertion, if you think any thing so silly worthy of a place in your valuable columns*.

Therein is portrayed one of those “rare” instances of success in that *extraordinary, difficult*, and uncommon operation, yecept reduction of dislocation of the humerus (of what kind does not appear). This case is one of so valuable a nature that I think it is the bounden duty of that eminent surgeon, Mr. Fergusson, whose case it was, or the “astonished” Mr. Steel, or the “apparatus bearing” Mr. Roberts, to publish forthwith the whole details of the interesting and novel operation to an admiring world, for the benefit of hospital and all other surgeons, and the “Colchester ones” in particular, “that this triumph of London hospital practice over provincial practice may be an additional inducement to the benevolent to support that public medical metropolitan

* We think one extract which our correspondent gives will be sufficient.—ED. GAZ.

institution known by the name of King's College."—I remain, sir,

Your obedient servant,

WHAT NEXT?

P.S.—We have just had a most wonderful case of that novel operation, phlebotomy! which I think of publishing forthwith in the Times and Morning Post.

STATISTICS IN MIDWIFERY.

By DR. METCALF.

PREMISING that the cases which are the subject of the succeeding remarks all occurred prior to the year 1839, I now proceed with the analysis of 300 cases of labour and delivery, upon which I attended as the accoucheur.

I. *The 300 cases of delivery gave birth to 302 children.*

II. *Of the duration of labour.*

The following table gives the duration of labour in hours; thus 1 woman was delivered in 1 hour, and so on:—

Hours in Labour.	No. of Women	Hours in Labour.	No. of Women.
1	1	24	56
2	1	25	1
3	1	27	1
4	7	28	2
5	3	29	1
6	25	30	7
7	5	32	1
8	15	33	1
9	1	36	14
10	8	40	2
11	4	42	1
12	85	47	1
13	5	48	1
14	3	50	1
15	6	56	3
16	2	60	3
17	4	65	1
18	8	66	1
19	1	67	1
20	7	69	1
21	1	72	1
22	1	85	1
23	3	90	1

The two most lengthy labours, those of 85 and 90 hours, were both cases of deformed pelvis, the sacro-pubic diameter being very greatly reduced. In one case, that of 85 hours, the child was expelled by the natural efforts, without the aid of art. The other was delivered by lessening the head and the aid of the blunt hook. As this was the only case of instrumental delivery, it will be seen that the use of instruments occurred only once in 300 cases. Whether this proportion be great or small, compared with

the practice in this country, I have no authority for determining.

III. *Presentation.*—The following table comprises all the different presentations; thus in 286 children the vertex presented, and so on:—

Presentation	No. of Children.
Vertex	286
Face	1
Face to pubis	1
Both feet	3
Foot and knee	1
Breech	3
Funis	2
Placenta	1
Not known	4

By the foregoing table, it will be seen that the natural presentations, allowing the four cases not known to have been preternatural, were 94.7 per cent. of the whole number, leaving only 5.3 per cent. for all presentations other than the vertex.

The *face presentation* occurred in a rapid labour, and gave no trouble in the delivery. There was nothing in the case worthy of note, save that I was sorely puzzled for a while to make out the presentation. The child's face was very livid, and did not assume its natural colour for some days.

The *face to the pubis presentation* occurred in a long and tedious labour. It was the first case to which I was called, after I came to this town, and was a miscarriage in the eighth month of utero-gestation occasioned by the brutality of a drunken husband: complicated as it was with a prolapsus of the funis, and stranger as I was to the practice of midwifery, as well as to the people among whom I had located myself, this case, as may well be supposed, gave me no inconsiderable uneasiness. It, however, terminated well; the child, from the prolapsus of and pressure upon the umbilical cord, was lost, but the mother had a speedy recovery.

Of the *three presentations with both feet*, two were lost after the descent of the child as far as the head. In the first case I was not called until after a midwife had exhausted her skill, if not her strength, upon the delivery, and the child was found quite dead upon my arrival. The delivery was completed without any difficulty, and the patient soon recovered. The other occurred in the early part of my practice, and with a fair trial, except the absence of the uterine contractions, I did not succeed in accomplishing the labour until the child was dead. Perhaps, but for certain vague fears of a dislocated neck, or having a child born minus a head, I might have accomplished the delivery in season to have preserved the child. As it was, however, I was too late, and I could plainly distinguish those convulsive motions,

described by authors, as preceding the death of the fœtus. The remaining case was delivered with but little aid, after a labour of twenty-four hours.—*American Journal of the Medical Sciences.*

PAINFUL AFFECTION FROM CUTTING THE WISDOM TEETH.

HAVING seen several cases of severe inflammation of the gums and the other soft parts surrounding the under wisdom teeth or dens sapientia, at the time of cutting those teeth; soon after I commenced the practice of dentistry (about 1820, and having also been a great sufferer in that way myself previously to my studying medicine,) I was led to seek a remedy for that painful affection: this inflammation is sometimes so great as to produce extreme pain at the junction of the jaws, and so much swelling and soreness of the surrounding soft parts (and extending to the throat) that the patient is hardly able to open the mouth, so as to give the physician an opportunity of even seeing the parts affected.

In such extreme cases I have used the depleting remedies both general and local with good effect; but my object at present is to show how to prevent such cases, or their recurrence, by pointing out their causes and applying the remedy at time.

The cause of this painful affection, when in its extreme cases, arises generally from the upper wisdom tooth having cut through the gum first (before the under wisdom tooth of the same side) and passing so low down as to rest on the lower gum, before the under wisdom tooth begins to cut through the gum; the upper wisdom tooth in some cases being from an eighth to a fourth of an inch lower (or longer) at its cutting (or grinding) point than the molars that is next to it. Now it will be readily perceived, that the first move of the lower wisdom tooth to cut through the gum (or any food or other substance pressing thereon, or the cheek or soft parts folding over or between the teeth) will produce irritation and inflammation which is aggravated by pressing the jaws together, and when the soft surrounding parts are once swelled they will frequently press forward over the jaws or tooth, so as to be pressed on when the mouth is closed, thus continually irritating the inflamed parts.

In some cases I have cut off the whole of the gum covering the top of the under tooth, with great advantage; but occasionally the tooth is so very far back, that the flesh back of the tooth and at the side, will press over the under tooth, and still continue to be

pressed upon or mashed, when the jaw closes so as to produce great inflammation of the surrounding parts, extending to the throat, and in some cases accompanied with great stiffness of the joint of the jaw. In all such cases as above, the upper wisdom tooth should be extracted as soon as possible, and the cure will soon be completed, and the recurrence ever after prevented, and the under tooth be freed from difficulty in arriving at its proper situation.

The above plan of cure I would recommend with great confidence, as I have seen a number of persons that had been occasionally sufferers for years, from the above affection, though they had been attended by some of the best physicians and dentists in this country, and some in Europe: one gentleman, an European, told me that his case had cost two hundred dollars in physicians' fees, and loss of business of at least a thousand dollars. This case as well as others was readily cured by extracting the upper wisdom tooth, and the use of some mild astringent and mucilaginous wash for the inflamed parts. In those cases the upper wisdom teeth are located so very far back as not to be considered a loss from extraction.—*Dr. Gunnel, in American Journal of Dental Surgery.*

SPINA BIFIDA TREATED SUCCESSFULLY BY REPEATED PUNCTURES.

THE tumor in this case was seated over the upper part of the sacrum, was about three and a half inches in diameter, and rose above the surface of the surrounding integument about two inches. The covering of the tumor was not healthy skin, but a peenliar thin membrane of a reddish colour traversed by numerous vessels like varicose capillary veins. The healthy integument formed a hard line at its point of union with the covering of the tumor. The tumor was punctured on the 17th, 20th, 21st, and 30th of October, with an iris knife, and from an ounce to four ounces of clear serous fluid escaped each time. The fluid was allowed to escape by drops—"at the rate of about three drops in a second; about a third, however, was always left behind. The escape of the fluid generally produced a sinking of the anterior fontanelle of the skull, but no bad symptom followed. After the last tapping the child became fretful and slightly feverish, the sac of the tumor became inflamed, and the child was observed to keep her left leg drawn up, and cried when it was touched. Slight spasms of the muscles were also observed, and tendency to

syncope whenever the head was raised. The tumor was kept wet with a spirit lotion, and gentle laxatives were given: the inflammatory symptoms abated, she returned to the country with her parents, and when seen two years after the operation, it was found that the fluid in the tumor had disappeared, and that a mass of indurated and corrugated integument covered the site of the tumor. The child was healthy.—*New York Journal of Medicine*.

CAUTERIZATION OF THE WOUND THE MOST EFFICACIOUS MEANS OF

PREVENTING THE OCCURRENCE OF HYDROPHOBIA.

M. DUPUY related to the Academy of Medicine, the history of a case where a person bitten by a mad dog escaped hydrophobia by having the wound freely cauterized. At the same meeting was related the fact, that, at Martinique, eighteen individuals were bitten by mad dogs during one year, that seventeen of these had their wounds freely cauterized and did not afterwards suffer, but that the eighteenth, who did not submit to this operation, was seized with hydrophobia. M. Leroux of Dijon has also published, as the result of his experience, that in that town all those who had been bitten by mad dogs, and had their wounds freely cauterized, have escaped, whilst all those who were not so treated have fallen victims to hydrophobia.—*Journal de Pharmacie*; and *Edinburgh Medical Journal*.

SPURIOUS SAFFRON.

WE have received information from several sources respecting the existence in the market of a spurious saffron, which has been offered at a very low price. In texture and general appearance it is like genuine saffron, of rather a dark colour, the light yellow filaments being absent. It imparts no colour to spirit or water, and we believe it to be saffron from which the colouring principle has been extracted.—*Pharmaceutical Journal*.

ADULTERATION OF BLUE PILL.

At the last pharmaceutical meeting, Mr. Mowbray incidentally stated that he had lately met with a sample of blue pill, in which stearine had been used in dividing the mercury, and substituted for a portion of the conserve of roses, a little otto of roses having been added to give it a flavour.—*Ibid*.

ON PNEUMO-THORAX :

AN ESSAY,

*Read (in part) at the Physical Society of
Guy's Hospital,*

By H. M. HUGHES, M.D.

One of the Assistant Physicians to the Hospital.

[Concluded from p. 503.]

CASE XI. — *Pneumonia — Emphysema —
Pneumo-thorax — Pericarditis — Adhe-
sion of the diaphragm.*

J. B., a tall, thin, but strong man, with light hair and eyes, by trade a baker, was admitted into the hospital December 8th, 1836. Four years before he had suffered from cholera, and a year after had an attack of inflammation of the chest, for which he was bled, and from which he speedily recovered. From that time he had enjoyed good health till about ten days previously to his admission, when, after exposure to wet and cold, he was attacked with cough, pain of the chest, rigors, and an inflamed and swollen state of the feet; for which he had been under medical treatment, but had not been bled. On admission his countenance was flushed and anxious, and the pupils dilated; his tongue was moist and white, and the skin cool. He complained of pain of the right side and shoulder, which was not increased on pressure. He had a distressing cough, accompanied with some expectoration of thick and very tenacious mucus; the pulse was 78, labouring, but not hard. In the lower posterior and lateral portions of the left side mucous and crepitating rattles were audible. They were also present, but less distinctly, over the inferior and middle portions of the right side posteriorly. The respiration was free on both sides anteriorly.

Ordered—V.S. ad $\frac{3}{4}$ iv.; Pil. Antim. Opiat. fort. c. Hydrarg. Chlorid. gr. ij.; Statim. post venesection. et vespere repend. si opus fuerit.

843.—XXXIII.

9th.—He was much relieved by the bleeding, and had passed a comfortable night; countenance greatly improved; complained of pain above the left clavicle; pulse 86; more free expectoration, small in quantity, pneumonic, mixed with bronchial mucus. Bronchophony and crepitation heard over the lower part of the left lung posteriorly. The blood was cupped and buffy.

Ordered Pil. Antim. Opiat. c. Hydrarg. Chlorid. gr. ij. 6ta quâque horâ c. Haustu. Jalep. Ammon. Acetat. et Vin. Antimon.

The next day he was so much better that the pills were ordered to be taken at bedtime only, and the draught to be taken as before. He continued to improve, so that on the 14th the pills were altogether omitted; but on the 21st, having complained of pain of the left side, he was ordered to be cupped, and was quite relieved by the operation.

On the 24th he had a troublesome cough, with watery mucous expectoration, and mucro-crepitation was audible in both lungs posteriorly; pulse 110, rather sharp; bowels confined; skin perspiring; tongue clean and moist.

Ordered—Pil. Hydrarg. gr. j.; Ext. Hyosciam. gr. j.; Pulv. Digitalis, gr. j. M. ft. Pil. ter die sumend. Rep. Haust.

His cough was relieved the next day, and the pills were omitted the day after. He continued to be occasionally troubled with a return of the cough, being alternately better and worse, till January 10, 1837, when in consequence of pain, and the sudden supervention of tubular breathing in the right side, he was ordered again to be bled, and to resume the medicines prescribed the day after his admission. He was again relieved; but on the 14th the operation was thought to be again necessary; the pills were changed for Hydrarg. Chlorid. gr. i.; Ext. Hyosciam. gr. $\frac{1}{2}$. 4ta quâque horâ, and a mixture prescribed containing Tr. Digi-

talis Mylij., for which was substituted, on the 19th, Mist. Cretæ, in consequence of relaxation of the bowels, together with a pill composed of Ext. Conii and Ipecacuanha for his cough.

The daily reports of the case are long, and would perhaps appear tediously prolix; I therefore pass to that of January 31st, when it was stated that he had passed a very restless night from great dyspnoea and difficulty of expectorating sputa, which had increased in quantity. He perspired profusely; was much emaciated, and had flushing of the cheeks; the pulse was 140, and small. The right side was exceedingly dull on percussion; and upon admeasurement was found to be an inch larger than the left. The ribs passed more horizontally outwards than natural, and were scarcely moved upon inspiration; the intercostal spaces were manifestly widened, but not bulging. Respiration was scarcely audible, and very distant, in the part affected.

February 3d.—Countenance much shrunk; breathing greatly oppressed; pulse very feeble and small; tongue clean; he had been delirious, and got out of bed during the night. A splashing noise was now for the first time heard on shaking the body; but no part of the side was discovered to be abnormally resonant on percussion. Dr. Davies' grooved needle (it having been previously introduced between the 6th and 7th ribs anteriorly without effect), was now passed into the chest between the 9th and 10th ribs posteriorly. A little serous fluid alone escaped. A small hydrocele trocar was afterwards used. Several ounces of sero-sanguineous fluid, coagulable by heat, slowly flowed through the canula, till it was introduced to its full extent, when there escaped in jets corresponding with the respiration, and much more freely than before, a large quantity of sero-purulent fluid, in which floated albuminous flakes. Six pints and a quarter were thus withdrawn, and the patient expressed himself as being much relieved. He then became faint, and the canula was withdrawn. The edges of the wound were drawn together by plaster, and a bandage applied around the chest.

Beef-tea and brandy were now taken; and subsequently a sedative draught was administered.

In two hours and a half after the operation, the expression of countenance had improved; the pulse was less contracted, and he felt better. He had a little sleep at short intervals, several times in the recumbent position, but in the evening the respiration was more hurried, and he was very restless; pulse 120, small, and feeble; skin cool. He was supported with beef-tea, isinglass, and wine; and was ordered to take a narcotic

draught at night, and some ammonia if required. The next morning he still appeared relieved, having slept three quarters of an hour on two occasions during the night. The cough was less troublesome, and the expectoration scanty; pulse 120, very small; respirations 46; amphoric breathing was now distinctly audible on the right side, and puerile respiration on the left side of the chest, and the sounds of the heart were heard on the right of the sternum. The bowels had not been moved for three days; the urine was scanty, with a copious deposit of the lithates. During the afternoon he became very restless, and awoke, after ten minutes' sleep, with spasmodic dyspnoea and "risus sardonius," which recurred three or four times before eight o'clock in the evening, when he expired. It was remarked that notwithstanding the large amount of fluid in the right pleura, the liver could on no occasion be felt below the ribs.

Inspection, 30 hours after death.

Chest.—The right pleura pulmonalis was very firmly adherent anteriorly to the parietes of the chest, inferiorly to the diaphragm, and posteriorly to spine and adjoining ribs, so that on removing the sternum it was necessary to detach the lung from the ribs anteriorly before the cavity of the empyema could be reached. On separating the adhesions which connected the lung to the fourth or fifth rib, a quantity of gas escaped. The cavity thereby opened into the sac of the pleura contained besides air about two pints of thick purulent fluid. The pleura was lined with a thick firm layer of fibrin, which was curiously arranged in parallel ridges to the intercostal spaces, like sand left by a retiring tide. The lung contained no tubercles. Though much compressed, it contained in some parts a little air, and was in other parts fleshy and oedematous. No opening was discovered in the pleura, but the investigation was not made with the blow-pipe under water. The aperture was not improbably concealed by the dense albuminous coating which encased that portion of the membrane which was in contact with the effused fluid. A separate and defined collection of sero-purulent fluid existed in the fissure separating the upper from the middle lobe of the lung, but in every other part the fissures were obliterated by old and firm adhesions. The diaphragm was greatly deformed, the pleura covering that portion of it which adjoins the inferior false ribs having contracted firm adhesions to the costal pleura, and thereby formed a boundary to the empyema. Below this it was not adherent; it thus preserved a small separate serous cavity made up of phrenic and costal pleura alone, which was free from purulent effusion. Towards the median line,

being also firmly adherent to the base of the lung, it was put upon the stretch by the pressure of the fluid above, and consequently deflected downwards. It thus formed a double layer of muscle and serous membrane, so that several square inches were removed from contact with the liver on its abdominal surface. The phrenic peritoneum was in apposition with itself, or was merely covered with a little plastic effusion, over the extent of surface thus curiously doubled up and projecting into the cavity of the chest; but beyond this it became re-adjusted to the convex surface of the liver. The left lung was glued to the thoracic parietes by some old pleuritic adhesions, the two lobes being partially joined together by well-organized false membrane. The costal pleura, with this exception, was healthy. The anterior edge of the upper lobe of the lung was somewhat rounded by emphysema, and near the apex anteriorly was a circumscribed indurated portion of lung, the size of a crown piece, extending about an inch into its substance. It was of a pale greyish colour, airless, unyielding, and apparently recently hepatized. The posterior portion of this lobe was tough, and upon being divided a quantity of frothy serum exuded from it. The bronchial tubes were not dilated. The lower lobe was scarcely so permeable by air as the upper, with the exception of the superior and posterior edge, which was tolerably healthy. The thick posterior portion upon section allowed the escape of a large quantity of serous fluid mixed with some which was more viscid and puriform, but was, notwithstanding, generally crepitant. The pericardium contained about two ounces of yellowish slightly turbid fluid, and near the apex of the heart were seen a few delicate bands of imperfectly organized lymph. The serous membrane itself was injected in some parts, and was universally rather opaque. The heart was rather large.

Abdomen.—The liver was large and myristicate, and its acute margin was of a very dark colour. No other morbid appearances were observed.

This protracted, severe, and perplexing case, for the recorded facts of which I am principally indebted to the notes of Messrs. Oldham and Cooke, who were successively clinical clerks at the period, has many remarkable peculiarities. Among the most striking, are the strange adhesions and duplicature of the diaphragm, which were probably the products of the most distant disease, and may possibly be ascribed to the inflammatory affection occurring some years before. These adhesions of the diaphragm to the ribs and to the whole of the base of the lung effectually prevented the descent of that muscle, and the consequent protrusion of the liver downwards and forwards by the

fluid accumulated in the pleura, and consequently deprived the observers of one of the most common characteristic signs of emphysema of the right side, according to the representations of Dr. Stokes. My own observation in other cases has not, however, induced me to place so high a value upon this sign as it has been supposed to possess by that gentleman.

Another remarkable peculiarity was the firm adhesion of the lung to the anterior parietes of the chest, which, together with those connecting it with the diaphragm, and the ribs adjoining the spine, prevented the total collapse of the organ; so that, notwithstanding the large amount of fluid and gas, the lung in some parts remained pervious to air and crepitant even to the last. Herein the case forcibly illustrates the statements made in a former part of this paper in reference to the preservative influence of adhesions in cases of pneumo-thorax, and resembled a case related by Laennec, in which the chest was similarly punctured, but no fluid evacuated, in consequence of similar adhesions of the lung to the costal pleura. At what time air escaped into the pleura could not be correctly determined, as no decided symptoms characterized the occurrence. But as the expectoration is said to have increased on January 31st, and Hippocratic succession was first noticed on February 3d, it is probable that it took place a few days only before the patient's death. As no aperture was found in the pleura, this case may be supposed to favour the notion of the formation of gas by the decomposition of the effused fluids: but to this opinion are opposed the facts of the fluid withdrawn by the trochar being destitute of disagreeable odour, and the occurrence of amphoric breathing after the operation. I have not myself the slightest doubt that with the expenditure of a necessary amount of care and trouble in the investigation of this case, the examination of which, as it was actually conducted, occupied a very long time, the opening would have been discovered.

CASE XII.—*Phthisis—Pneumo-thorax—Emphysema—Death after nine weeks.*

(Very beautifully drawn up by my young friend Mr. Weston, now in India, and reported almost entirely in his own words.)

J. S., aged 32, a rather emaciated man, of sallow complexion, with dark hair and eyes, by occupation a labourer, was admitted into the hospital, April 3d, 1839. He had been accustomed to work hard and drink freely, sometimes as much as two gallons of beer a day. His mother had died of phthisis, but the rest of his family had enjoyed good health. Sixteen years ago he suffered from ague, and he had since had three attacks of

rheumatism. For the last nine or ten years (the first two-thirds of which period he spent near Chichester, and during the last third had been working in the Dock-yard at Woolwich) he had been subject to cough, which for the last twelve months had been much more frequent, and accompanied with increased expectoration, dyspnoea, gradually progressive emaciation, and perspiration upon waking in the morning. While in nearly the same condition as in months passed, he was, during a violent fit of coughing three weeks ago, suddenly seized with severe pain in the lower part of the right side of the chest, accompanied with great dyspnoea, which lasted for three or four hours. At the expiration of this period he felt a little easier, though not free from pain and shortness of breath. Thus he continued till the next morning, when he awoke with pain as severe as before. Some internal medicines were administered, and a blister applied, which produced a mitigation, but not a cessation, of his suffering, which had continued more or less ever since. The expectoration, which before was copious and muco-puriform, had since been trifling, but it had been, once or twice, streaked with blood. On these occasions only had he ever noticed any blood in the sputa. Before his present attack he never tried to lie upon the right side, as he was accustomed always to lie upon the left; "but during the whole of his present illness he has found it impossible so to lie." For the last five weeks he had been unable to lie even upon the left side, and had consequently kept upon his back. The breathing, except at the onset of the malady, had not been shorter than it was before. During the last week or ten days he had perspired at night more profusely than usual, but it did not appear that he had had any distinct hectic paroxysms.

Upon admission, he complained chiefly of pain in the lower part of the right side of the chest, increased upon pressure. His cough was only occasional, and his expectoration rare and scanty. The breathing did not appear much oppressed—respirations twenty-six in the minute; the pulse was regular, small, easily compressed, 120 in the minute; the skin was cool and rather harsh; the tongue moist, but slightly furred; the bowels open.

Physical signs.—In the recumbent position, the lower two-thirds of the right side of the chest were much too resonant on percussion. The upper third of the right side, and the whole of the left side, yielded a natural resonance. On applying the ear or stethoscope over the lower two-thirds of the right side, no respiratory murmur was heard; but amphoric respiration and metallic tinkling were audible, with occasional metallic resonance of the voice, and cough. At the upper part of the right

side, at a spot just below the clavicle, there was cavernous respiration and very marked resonance of the voice; and around this spot there was muco-crepitation. On the left side of the chest, anteriorly, the respiration was puerile, especially over the upper half of the lung; below it was accompanied with a little cooing murmur. When the patient sat up in bed, the lower two-thirds of the right side, anteriorly, still sounded too resonantly on percussion; and in the middle third amphoric respiration and metallic tinkling were still heard. The upper third of the lung afforded the same signs as when he was lying down. Posteriorly, the entire chest sounded naturally resonant on percussion, except at the lower part of the right side, which was rather more dull than natural. At the lower third of the right side there was absence of respiration; in the middle third amphoric respiration, metallic tinkling, and metallic resonance of the cough; and above the spine of the scapula increased resonance of the voice, cavernous respiration, and muco-crepitation. On the left side the respiration was puerile, and at the upper part accompanied with muco-crepitation. Succussion caused a decided fluctuation of fluid within the right pleural cavity. The fluid was not only heard distinctly to splash against the parietes of the chest, and a metallic tinkling to follow the splash, but the agitation of the wave, caused by the succussion of the contained fluid, was distinctly felt by the hand, and by the patient himself. Upon admeasurement there was no appreciable difference found between the two sides of the chest. The heart was heard to beat in its natural position, and nothing morbid was observed respecting it, with the exception of its action being too rapid. The liver was not felt below the ribs, nor was the spleen perceptibly enlarged. Ordered—

The pain of the side was removed by the cupping; but I find no other circumstance worthy of record in the progress of the case till his death on the 5th of May, six weeks after his admission to the hospital, and nine weeks after the supposed occurrence of pneumo-thorax.

Inspection, 24 hours after death.

The body was considerably emaciated. The head was not opened. *Chest:* The right pleura pulmonalis was superiorly connected with the parietes by a few old adhesions. The pleura was in other parts covered with a thick, soft, and whitish albuminous layer, and contained about 21 oz. of sero-purulent fluid. The remaining space not occupied by the greatly contracted lung was filled with gas. The lung was reduced to the size of a very

large orange, and had in several parts small conical cavities and tubercles in various stages. On its anterior surface were three small rounded openings connecting as many small vomiceæ and bronchial tubes with the cavity of the pleura. On the left side old adhesions almost entirely obliterated the pleural cavity. The lung was, in most parts, sprinkled with tubercles, and contained in the upper part a few small cavities filled with dirty purulent fluid. The larger bronchial tubes were greatly obstructed by purulent mucus, and the smaller tubes were much dilated. The pericardium contained about one ounce of serum, but, together with the heart, was otherwise healthy. *Abdomen:* The liver was large, congested, and granular; the spleen was also large and firm. The kidneys were simply congested, but their tunics were unnaturally firmly adherent. The stomach, and the small and large intestines, were healthy.

In the preceding case is presented a fair example of pneumo-thorax in its more common form, the accession of which was well marked; and the general symptoms and physical signs accompanying the progress of which were exceedingly characteristic, and correctly reported by Mr. Weston. The lung, though containing several small cavities, was adherent to the parietes only to a small extent, and, as was indicated by the small size to which it was reduced, was not much consolidated. Hence the space admitting the collection of air in the pleura was comparatively large, and hence the symptoms occurring when the accident took place were comparatively severe. But as the apertures, though small, were three in number, and were also round and free from obstruction, and therefore admitted of the free egress from, as well as the ingress of the air to the pleura, the distressing symptoms were not of long continuance. Caused by the sudden change of the circulation, and accumulation of blood on the right side of the heart, in consequence of a large portion of the respiratory organs becoming, in a great measure, inefficient for the purpose of aerating that fluid, they gradually diminished as the circulatory and respiratory organs became slowly adjusted to each other. No accumulation of air occurred, or, while the openings continued unobstructed, could occur in the pleura. The side was not dilated; the heart was not displaced; the liver was not protruded; the operation of paracentesis would necessarily have been useless. The man, indeed, was generally able to walk about the ward, and converse with his fellow-patients, and sank at length more from the effects of phthisis than of pneumo-thorax.

In the preceding pages I have said scarcely anything in reference to the treatment of

pneumo-thorax, as I believe that no plan of treatment can be recommended as even generally applicable to the constantly varying and variable conditions under which the disease appears. Each case must be separately studied; the symptoms of each individual must be viewed in connection with the previous history and the physical signs; and the indications presented by each must be met by means appropriated, not to the name of the complaint, but to the actual condition of the patient at the time. In one case the disease may be accompanied with acute pleurisy, and local bleeding or even venesection may be required; in another, the most powerfully diffusible stimulants may be imperatively demanded, to prevent exhaustion and death. In some instances accompanied with a large accumulation of gas or fluid effusion, paracentesis may be advisable, for the purpose of affording at least temporary relief; in others, the operation will not be attended with the slightest momentary advantage; it will be worse than useless. I have therefore thought it better to pass by the question of treatment almost entirely, rather than to introduce that which might possibly lead to error. In all cases it may be, however, observed, that perfect quiet and rest are most important remedial measures.

I have not entered into a consideration of the possibly remedial tendency of pneumo-thorax and empyema in some cases of advanced phthisis, in which little disease exists upon the opposite side, as I have desired that my statements should be as free as may be from mere hypothesis, and be regarded as (what, indeed, they really are) the pure results of observation. I am, moreover, not aware that I am able with advantage to add anything to the remarks already published upon this matter by Drs Houghton, Stokes, Barlow, and myself. I cannot, however, allow this opportunity to pass without a brief allusion to this very interesting question, and without referring to the very marked improvement that has sometimes taken place, after the immediate effects of the accidental rupture have subsided, in the symptoms and comfort of persons in the latter stages of consumption, in whom pneumo-thorax has supervened. Hectic fever, previously common, has been observed to cease; the cough, before frequent, manifestly to decrease, if not entirely to disappear; and the expectoration, which had been abundant, to be so much reduced as to be scarcely observable. These consequences of the accident cannot, indeed, be deemed wonderful, when it is recollected that an organ in a state of active disease, and perhaps of inflammation, containing abscesses with large secreting surfaces, is, by the pressure of the gas upon its exterior, so

collapsed as to be rendered inactive; that little or no air enters its vesicles, and that the blood permeating its vessels is reduced almost to a minimum; that the diseased organ becomes quiescent, and the whole function of respiration is carried on by one which is comparatively healthy. I think, indeed, that there can be little doubt that, in some few instances, life has been prolonged by the occurrence of this accident, though it has been regarded as a speedily fatal complication to phthisis by some of the French pathologists.

Scarcely anything has, in the preceding pages, been said in reference to prognosis, and nothing respecting the curability of the affection, as I believe we are not at present in possession of any facts amounting to a *proof* that it has ever been cured, or, indeed, that it is really susceptible of cure. Dr. Houghton has, as it appears to me, with great propriety, briefly alluded to its curability. There seems, indeed, nothing in the nature of the disease itself which renders it unsusceptible of cure. There is nothing, with which I am acquainted, in morbid anatomy or pathology, which is opposed to the possibility or even the probability of such an occurrence. If, for example, in the cases of Dr. Townsend and Andral, or even in cases III., IV., and X. in this paper, simple pleurisy had followed, and by the effusion of plastic lymph had sealed up the aperture; if, by perfect rest, this lymph had subsequently become organised, and adherent to the costal pleura, and a permanent barrier had thus been formed against the farther ingress of air to the serous membrane; as it is known by experiments upon the lower animals that gases may be absorbed from these membranes, and it is a matter of almost daily observation that fluid effusions are thence absorbed, there does not appear any reason to doubt that it is at least within the range of a not very remote probability, that the pneumo-thorax might have been removed, and the disease thus far absolutely cured. Cases, indeed, sometimes occur, which, to the attendants, seem to indicate that such a process has actually taken place. But in such cases as in phthisis, when recovery is established, though there be no dispute as to the previous existence of disease, and of extensive disease in the lung, doubts will be expressed by readers or auditors, and will occasionally occur to the minds of the observers themselves, whether that disease was really phthisis in the one case, or pneumo-thorax in the other. An instance of this recently occurred to myself. A young married lady, several of whose brothers and sisters had died of phthisis, and who had herself for some months been in delicate health, was after an abortion attacked with severe febrile symptoms, ac-

companied with relaxation of the bowels, by which she was much reduced. She had not been previously troubled with cough, nor had she ever suffered from hæmoptysis, and her chest had been pronounced by more than one examiner free from disease. Her attendant during the attack under consideration thought differently, and I was requested to see her with him in consultation. I found her much exhausted; she had recently passed large quantities of sanguineous fluid, mixed with alimentary matters, from the bowels; her features were contracted, and her eyes sunken; copious perspirations existed on the face, and she had a clammy state of the surface; the respirations were 45, and pulse 140 to 160 in the minute, and so feeble as scarcely to be felt. She had no cough, nor had she suffered from any; and, though her respirations were so frequent, her voice was tolerably firm and steady. In this condition a minute exploration of the chest could not of course be made, and would not have been justifiable; but as I knew that its condition was a source of great anxiety, and that my opinion would be requested thereon, I made such examination as the state of the patient permitted. I found the left side free from abnormal signs, and the right tolerably resonant on percussion, except at the lower and posterior part. This side was but slightly moved upon inspiration; and the respiration was hoarse below the clavicle. Posteriorly and inferiorly the breathing was tubular and fistulous, and the voice so shrill as to approach to metallic resonance. Such alone were the facts which I was then able to collect. She was ordered opiate enemata, and large doses of acetate of lead and opium, with such occasional stimulants and fluid nutritious diet as she was able to take. The next day she was in some respects better, as the dysenteric diarrhoea had been much moderated; but on the following day she was still lower than before. Her exhaustion was now extreme; her respirations 60, and her pulse as nearly as it could be counted 160. She appeared, indeed, almost beyond a justifiable hope of recovery, but was ordered large doses of ammonia and opium, with mucilage, and infusion of serpentary or cusparia, every three hours; to have the enemata administered if required, and to take brandy and water and nourishment frequently. By these means, together with perfect quiet and excellent nursing, to the great surprise of her friends, and the still greater surprise of her medical attendants, she began slowly to recover. The affection of the bowels was no longer troublesome; but as there could be no doubt whatever of the existence of serious and extensive mischief in her chest, her ultimate recovery was considered and stated to be exceedingly problematical. As to the exact

nature of that disease, the considerations of her belonging to a phthisical family; of her having been previously examined, and stated to be free from thoracic affection; of her never having suffered from cough, or, to her recollection, from pain of the affected side; together with the exceedingly rapid breathing and extreme collapse, perhaps caused by the serious drain on her system taking place by the bowels, led me to suppose that the complaint in the chest was pneumo-thorax. I did not visit her again for about two weeks, when she had much improved, and the dysenteric affection had long ceased. The pulse was still 140, very small and feeble, and the respirations 40 in the minute; the skin soft and clammy, and the features pinched, though the expression of countenance had much altered for the better. On exploring the chest I still found the left side free from the evidences of disease. The right was almost motionless upon inspiration; it was generally not dull upon percussion, and anteriorly was rather more resonant than natural, except below the clavicle. It was destitute of pure respiratory murmur in every part. Tubular breathing existed anteriorly, even below the clavicle, and over the scapula posteriorly; while below that bone the breathing was decidedly fistulous, and the voice shrill and metallic. Hippocratic succussion was not present. She has for the last three months been very slowly, but, with one brief exception, gradually improving in health and strength, and she is now able to walk out, to join her family circle, and to engage in the lighter domestic duties of her establishment without inconvenience. I have not examined her chest, nor seen her in a medical capacity, since the occasion last referred to; I am therefore unable to make any report upon the present state of the lungs and circulation, though I was informed by her medical attendant that for some weeks, or even months, the pulse had continued exceedingly feeble, small, and rapid. The facts of her case, so far as they are here related, are those that I myself observed. I am unable to account for them, excepting upon the supposition of the thoracic affection having been pneumo-thorax, and of its being either cured, or so much reduced in amount as to be comparatively harmless.

CONCLUSIONS.—From what has been stated in the preceding pages, and for the most part illustrated by the cases therein related, the following conclusions may, I think, be fairly derived:—

1. That pneumo-thorax is often not so speedily fatal as has been represented, especially by the French pathologists.

2. That the decomposition during life of effused fluids, and gaseous exhalations from

the pleura, are, to say the least, doubtful causes of pneumo-thorax.

3. That pneumo-thorax has not been proved to arise from other causes than a communication of the pleura with the external air.

4. That the most frequent causes of pneumo-thorax are phthisis, empyema, and gangrene of the lung, in the order in which they are mentioned; and that, independently of external violence, pneumo-thorax from other causes is extremely rare.

5. That pneumo-thorax occurs as a consequence of phthisis, with a very small cavity, or without any cavity, existing in the lung.

6. That according to the records at present possessed, pneumo-thorax is more frequent in males than females; and the right side of the chest is rather more frequently affected than the left.

7. That urgent dyspnoea and great prostration do not necessarily accompany the accession of pneumo-thorax.

8. That pneumo-thorax may take place without the occurrence of any symptoms by which the period of the accident can be positively determined.

9. That tympanitic resonance on percussion, and absence of respiration, are not pathognomic of pneumo-thorax, as these physical signs may exist without pneumo-thorax, and pneumo-thorax may exist without these signs.

10. That pneumo-thorax is generally easily recognized by physical signs, but that even with their assistance the diagnosis is sometimes difficult and uncertain.

11. That the absence of the symptoms which usually supervene upon the occurrence of pneumo-thorax, and of the physical signs which generally accompany it, is probably dependent upon the presence of a considerable amount of disease existing in the lung, upon extensive pleuritic adhesions, or upon the two combined.

12. That the greater the amount of disease in the lung, and the more extensive the adhesions of the affected side, the less marked are probably the symptoms of the attack, and the less characteristic are the physical signs of the disease.

13. That enlargement of the side, displacement of the heart, and protrusion of the liver, are not necessary accompaniments of pneumo-thorax.

14. That the preceding symptoms, when present, are probably dependent upon the opening into the pleura being of small size, or being obstructed, or upon fluid effusion, as they do not usually occur in simple pneumo-thorax when the opening is large or free from partial occlusion, or when the fluid effusion is not considerable.

15. That the operation of paracentesis is

not to be recommended in pneumo-thorax, except for the purpose of relieving urgent symptoms, arising from the accumulation of gas, or of removing the fluid effusion which accompanies it.

16. That the general treatment of pneumo-thorax must depend upon the symptoms presented by the individual case, but that in all cases, and under all circumstances, perfect rest is likely to be attended with advantage.

17. That it is probable that the supervention of pneumo-thorax in some cases of advanced phthisis has tended to the prolongation of life.

18. That there is no valid reason for believing that pneumo-thorax is unsusceptible of cure, and that it is therefore necessarily incurable.

SOME OBSERVATIONS
ON THE
ANATOMY OF THE INGUINAL
CANAL.

BY ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

(For the Medical Gazette.)

THE following remarks contain the substance of a lecture I have been in the habit of delivering now for several years, on some disputed points in the elementary anatomy of the inguinal canal. After the publication of Mr. Guthrie's original memoir, I still continued to doubt the fact of any *distinct* muscular fibres having been ever seen in the situation described by that distinguished surgeon and anatomist; but a case did at last occur in which such a muscle actually existed; and I have felt it to be a duty to my students, and to myself, to state that no doubts whatever now remain in my mind of the perfect accuracy of Mr. Guthrie's dissections.

Although many practical and good surgeons consider the anatomy of the inguinal canal, its coverings, walls, and fascia, as a matter of but little moment in practice; yet it cannot be denied that many very distinguished operators have thought otherwise, and have published memoirs and treatises not only on the pathology of the canal in question, but also on its minute healthy anatomy; implying that they deemed the determination of its structure a

matter which would not, and ought not, to be discussed in an off-hand way. But perhaps, after all, the disregard shewn to the minute anatomy of hernia, as it is called by certain surgeons, is intended to be applied merely by them to the coverings of the hernial sac, without any reference to their elementary structures, forming the walls of the inguinal canal; for it is to be presumed, that scarcely any one would venture to assert that even this degree of knowledge was not required by the surgeon, to guide him safely in his operations on hernia, whether by the knife or the taxis—to investigate the pathology of unfortunate cases—and to contribute his share, however small, to the onward progress of the science and of the art.

It is under this impression that I humbly venture to think, that notwithstanding the authority of some distinguished surgeons, the minute anatomy of the elementary and normal structures composing the inguinal canal affords a fair subject for investigation in a practical point of view, independent of all other considerations.

That I may not be mistaken as to what is proposed in this memoir, I beg, *in limine*, to state it to be my intention to limit what I have to say altogether, or nearly so, to a consideration of the different forms and arrangements assumed by those portions of the internal oblique and transversalis muscles which are more especially connected with the canal; or, in other words, their inferior margins, and their mode of attachment to the pubis, and to the inner surface of the crural arch.

This examination will be found to include, I apprehend, some points of considerable interest, and a few, perhaps, of even a strictly practical bearing.

1. The obliquus internus and transversalis muscles are connected inferiorly, or have an origin, in the usual language of the anatomist, from the internal or concave surface of the crural arch. The extent of this origin varies, also its form or nature; and this happens in respect to both muscles; for, without pretending to enumerate all or half the varieties which occur here, it may be shortly stated that, commencing at the anterior and superior spinous process of the ileum, it may extend inwards—that is, towards the pubis—for

a full half, and even more, of the inner surface of the crural arch; or it may be limited to an inch or so of the same surface.

Again, both muscles (I mean, of course, the obliquus internus and transversalis) may extend equally low down, and be co-extensive in their attachment to the crural arch, or one may be there imperfect and shorter than the other; and this may happen either to the obliquus or to the transversalis; an inequality extending also to their tendons, even to that portion found behind the middle of the rectus muscle, and forming the posterior wall of its sheath, where occasionally it will be found that one tendon obviously stops short of the other; and this seems to happen most frequently, but perhaps not exclusively, to the obliquus. Besides this, the attachment of these muscles to the interior surface of Poupart's ligament varies also exceedingly in respect to their connection or union with the cremaster muscle; for sometimes there runs a distinct and common tendon, for the space of at least an inch, between the obliquus and transversalis on one hand, and the cremaster; and very often there is no such tendon. Occasionally it is somewhat difficult to say what fibres belong to the cremaster, and what to the abdominal muscles; nor will an appeal to the other extremity of the cremaster always solve this difficulty (although it generally will, for an obvious reason), inasmuch as a few scattered fasciculi of these doubtful or indeterminable fibres may actually follow the cord, as if they truly belonged to the cremaster, but quit it previous to reaching the external abdominal ring, and return, forming a loop to be attached to the pubis, upon the surface of the conjoined tendons.

2. It being admitted that these varieties in the conformation of the lower margin and inferior origin of these two abdominal muscles are met with, I have next to consider the progress of these muscles along the upper edge of the inguinal canal, over or superior to the spermatic cord, at its exit from the deep ring (ring of the fascia transversalis) towards the pubis and linea alba, in which they terminate by expanded tendinous fibres. But here arises an important question, and a much disputed one: do all the fibres of both muscles run over or superior to the

spermatic cord, at its exit from the deep ring, or at least may be made to appear so, and to do so in reality, by a little dissection, a clearing away of a little cellular substance, and a cautious use of the handle of the scalpel? This question I endeavour to answer in this way. Shewing by dissection, exposed in the usual way, the inguinal canal and the cremaster muscle running through it, divide this muscle about half an inch above its passage through the external ring; this will enable the dissector to draw it fairly out of the canal, exposing the concavity or rather internal surface of the ligament of Poupart; and if he at the same time draws upwards and somewhat inwards the spermatic cord, he will expose the posterior wall of the inguinal canal throughout about one-half at least of its external portion. Now this wall he may, and probably will find, in a hundred consecutive dissections of this part, to be formed mainly by the fascia transversalis, and by its union with the crural arch and femoral aponeurosis. Further to satisfy himself on this point, let him cautiously dissect away from its somewhat varied origins and connections, the whole of the cremaster muscle, and still he will find that the posterior wall, at the part I now speak of, is not muscular.

But the question is, I presume, not as to what it usually is, which, beyond all doubt, is what I have now stated it to be, in conformity with the concurrent testimony of nearly all anatomists; but is it ever otherwise? or, in other terms, is it ever muscular? Are muscular fibres ever found in this situation, towards the upper and outer extremity of the inguinal canal, independent of the cremaster, no matter how arising, whether from a tendon common to these with the obliquus and transversalis, or arising disjointedly and separately from the inner surface of the crural arch, and descending in the canal towards the pubis, upon the fascia transversalis, inferior to the deep ring, and consequently placing that ring, with its constant and occasional accompaniment—that is to say, the spermatic cord and the bowels in hernia—in the peculiar position of an opening, which, if not a muscular opening, which it could under no circumstances be, at least an opening having muscular fibres above, and

muscular below it, practically influencing surgical considerations respecting the structure and form of the opening itself? Now this question has been answered in the affirmative by two anatomists, Mr. Guthrie and myself, with this difference, however, that the one considers it to be a rather common occurrence; the other states it to be so rare, that of hundreds of dissections performed by him, he has but once observed the presence of this additional muscle, or portion of muscle. The individual case was shewn to me; the presence of the muscle could not be doubted. In this instance, then, the spermatic cord, at its passage through the deep ring, did pass through a muscular opening the instant it had escaped from the deep ring. Had hernia been present, it might have been liable to strangulation from the action of the muscular fibres above and below the neck of the sac; but surely not of a kind demanding any remedial means beyond an active bleeding and the taxis, aided by a favourable position of the trunk.

3. How do the margins and inferior portions generally, of the internal oblique and transversalis muscles, terminate mesially, that is, towards the pubis and linea alba? The anatomy of the tendinous terminations upon and above the pubis being subject to a constant and great variety, has also given occasion to much discussion and dispute, depending mainly, it is to be presumed, on this circumstance, common enough in all these matters, that each anatomist took for granted that the arrangement he had himself always observed was likely to be the constant or normal one; and that which he had not seen, after much dissection, was, at the very least, open to great doubt; or, at all events, would be viewed merely as a variety or anomaly, interesting in an anatomical and physiological point of view, but, from the very rarity of its occurrence, wholly inapplicable to practice.

I shall now take the liberty of stating, as briefly as I can, those varieties which have been shewn me in regard to the mesial terminations of the fibres of the internal oblique and transversalis muscles.

But previous to considering the mode in which the internal oblique and transversalis muscles terminate

internally, that is, towards the pubis and linea alba, I shall offer a few remarks respecting their varying form whilst descending along the upper part of the inguinal canal. When the tendon of the external oblique muscle is cut through, and laid down towards the thigh in the usual way, the contents of the inguinal canal in the male are first seen loosely inclosed in a delicate cellular tissue; the external spermatic nerve comes first into view, and on cautiously clearing away a little of the cellular tissue, the fibres of the cremaster, and the lower edge of the internal oblique, become soon distinct.

If these muscles be now carefully separated from each other, about the middle of the canal, the inferior fibres of the internal oblique and transversalis will be found even here to present a very great number of varieties; for sometimes a distinct and well-marked edge may be made out without difficulty; at other times the muscular fasciculi become pale, attenuated, tendinous even; begin to spread out, and terminating separately by extremely delicate fibres, proceed onwards to their destination in the linea alba and pubis. My attention has often been directed to these fibres. Unless carefully dissected, they will at first sight appear to run behind the spermatic cord, and not over it; and this circumstance has often led, no doubt, many to believe in the comparative frequency of such an arrangement; whereas, as we have already seen, it is exceedingly rare, probably not occurring once in five hundred dissections. However this may be, for I pretend not to speak statistically regarding it, these fibres require always a very careful dissection.

I shall now proceed to consider the mode in which these two muscles, the internal oblique and transversalis, terminate internally, or towards the middle plane of the body. The varieties occurring here may be reduced to three.

First, the muscular fasciculi of both muscles terminate by long and delicate tendinous cords attached to the symphysis pubis and crest inferiorly, and to the linea alba above, forming the conjoined tendons of anatomists. When this happens there exists naturally, but not always, a triangular fascial expansion connected on one hand to the cellular sheath of the rectus and pyramidalis muscles, and on the other to

the crest of the pubes, rather internally and posteriorly, and to a certain extent at this point a small portion of the fascia transversalis; this is the triangular and semilunar fascia of modern anatomists. With respect to this semilunar strengthening of the structures, nothing can be more varied; for sometimes it is of considerable strength; at others weak, like cellular tissue: thus, it is in the strict sense of the word a constant part, yet its presence or absence must influence a good deal the production of the direct inguinal hernia.

Secondly, the lowermost fibres of the internal oblique and transversalis muscles, may, in addition to the usual termination of their tendons in the pubes and linea alba as conjoined tendons, transmit a series of semicircular and concentric fibres behind the internal portion of the spermatic cord, either to a small extent, which is common enough, or so large and broad as to form a distinct semilunar muscular or tendinous expansion, situated behind all the lower part of the spermatic cord, having the form of the so-called semilunar fascia, doubling it in fact, and probably taking its place when strong.

Now, this semilunar portion of these muscles, thus forming the posterior wall of the inguinal canal, towards its lower half, may be either tendinous or muscular, narrow or broad, directly attached to the crest of the pubes, or indirectly. When very broad, as I have seen it twice, it produces the curious appearance of a muscular ring or aperture, through which the spermatic cord is passing. To do away with this deception, it is only necessary to cut through the spermatic cord a short way above the external abdominal ring, and drawing it outwards, so as to expose the posterior wall, the semilunar portion of the internal oblique will come fairly into view, and it becomes manifest that the muscular ring so formed by the attachment of these muscles to the crest of the pubes forms but an imperfect ring, even in this sense.

Before concluding this hasty sketch, I may take the liberty of discussing the practical question, does the spermatic cord in any individual pass in its course whilst entering, situated in, or emerging from the inguinal canal, through an opening or ring, whose edges are muscular; or, in other terms,

does the spermatic cord immediately on passing the deep or internal inguinal ring (ring of the fascia transversalis) likewise pass through a *muscular opening* formed by a splitting of the internal oblique, or of the transversalis muscle, or of both. Now, I have already remarked that this may occur; that in fact it has occurred; but so very rarely, that it seems to me scarcely a practical question. I allude, of course, to its bearing on that form of hernia called the *indirect inguinal*, which descends in the course of the spermatic cord. But it is also possible that the spermatic cord (and hernia when present) may pass through a muscular opening formed in three ways; first, by the presence of muscular fibres above and below the deep ring so arranged as more or less completely to enclose the cord; the form of the opening will be an elongated narrow slit; secondly, the termination of the conjoined tendons, as they are usually called, may be so broad and expanded, as to run behind that portion of the cord lying behind the external or superficial ring, and forming thus the posterior wall of the lower inguinal canal, extend outwards by concentric semi-circular fibres, until they approach within about an inch of the lowermost fibres of the internal oblique and transversalis, as they arise from the inner surface of the crural arch. Now this arrangement is not so unfrequent as the first, but the muscular ring so formed is not so complete; or, lastly, both sets of fibres may meet upon the posterior wall of the inguinal canal, and thus form a complete muscular ring. But such an arrangement I have not seen, nor am I aware of its having been described. In conclusion, all consideration as to the result of these arrangements, in how far they influence surgical practice in respect to strangulated indirect inguinal hernia, I leave to the practical surgeon, who alone can properly decide on their value.

RECORD OF CASES.

By THOMAS MAYO, M.D. F.R.S.
Physician to the Infirmary of St. Marylebone.

THE march of science in medical philosophy must be from individual instances to general propositions. In the application of the proposition to prac-

tice, the direction of thought is reversed. But we should err, if we limited the science of medicine by this description of it: for, *pari passu* with the procedure thus noticed, and subsidiary to the application of the principles thus acquired, another highly scientific operation is demanded. Indeed, the march of science towards the formation of general principles will be practically valueless, if the above mentioned procedure be deemed all-sufficient; if an enquiry be not at the same time vigorously conducted as to the shades of difference which separate from each other, and individualise, cases of the same kind. In the first point of view in which I have placed this subject, we deal with facts in relation to their common points; but in this second point of view we have to deal with them in relation to their discrepancies. The first operation is statistical in its nature, and would lead to an indiscriminating practice: the latter operation unties the facts thus accumulated, and subjects them to an ordeal which is requisite to their exact use.

I make the above remarks, in order to obtain their just place and importance for an enumeration of cases. Thus individualised they possess, perhaps, a less philosophical air, than in their statistical character. But their utility is obvious. Indeed, the practical character of the English mind has largely enriched our medical literature with cases contemplated in this point of view. We abound in most valuable monographs. Such, then, is the point of view in which I wish the following cases to be regarded, however inferior they may be in quality.

But, in reference to the publication of cases, there is another consideration, to which I would gladly call attention; and I trust I have not altogether failed, if I shall stimulate other members of the profession to take it up themselves.

If a discovery be made by a physician in pathology or therapeutics, he records it by publication. If he has lectured ably and successfully on pathology and therapeutics, he publishes his course of lectures. In the first case, the practice laid down will be peculiar, but it will relate only to the immediate department of medicine in which the discovery is made: in the

latter case the practice laid down will be studiously general. It will represent the prevailing practice of the day. But we want *also* the practice of the individual physician. Eminent physician rises after eminent physician, runs a beneficial course, and dies without leaving a memorial of his habitual method of practice, except in the decaying recollection of his contemporaries. We may justly lay claim to a very improved state of pathology in the present age. But, how gladly should we receive information, if such could be given us, how a David Pitcairne, a Warren, or a Baillie, treated certain combinations of symptoms, and with what event. The agents suggested to the medical mind by a survey of disease, viewed from different aspects, and on different hypotheses, will have interesting differences, which such records of practice alone could adequately lay before us.

In the enumeration of benefits that may result from published cases, we must not leave out one, implying, indeed, humble merit in the publisher, but of very considerable value to a class of perusers. Every student must have been aware of the value of a hospital case-book. The publication of such a record of pathology and practice would be of great value, and not the least so in presenting to him ordinary cases. The cases usually recorded in our journals are placed there because they are remarkable, and therefore of less frequent occurrence. So far, then, as this source of information is concerned, his daily wants, such wants as every one must have felt at the commencement of practice, are left unsupplied.

The following publication may in some measure contribute to the supply of these wants, since cases of ordinary occurrence fall plainly within its scope. Let it be remembered that the most ordinary case, if faithfully given, as far as the description goes, is illustrative, either by contrast or resemblance, of all other cases under the same head.

Cases of Peritonitis, &c.

Ann Chesworth, aged 8 years, a thin pale girl, with a very anxious eye, and distressed look, was admitted into the St. Marylebone Infirmary, the 21th of September, 1842, having been ill two days. She was constantly crying and fretting, but made no definite complaint. There was a quick small

pulse, a hot head, restlessness, some distension of the abdomen, and some tenderness; not easily recognised, indeed, as she complained, wherever she was touched. I saw her on the 25th: she had been much relieved the day before by leeches applied to the temples. Hydrarg. Chlorid. grs. iij. had been given her every sixth hour. She was passing by the bowels green shreds of faeces, and had been doing so before the calomel was first given. Vomiting, which had before existed, is relieved. Pulse small and quick.

26th. — Continues free from sickness; fretfulness abated; faeces continue green.

Sumat. Hydrarg. cum Creta, grs. ij.; Hyd. Chlorid. gr. j. bis quotidie.

October 1st. — Other symptoms remaining the same, I observed that respiration was quickened, and was informed that she had coughed during the night. Examining the thorax, I found extensive small crepitus and deficient vesicular penetration in both lungs, principally in the right. Conceiving this to be intercurrent pneumonia, I applied a large blister interscapulus, and continued the mercurials. The quickened state of respiration was the only additional symptom which occurred. Her general appearance, and state of pulse and skin, was that of simple fever. There was no delirium, but constant fretfulness, and an aspect expressive of distress. The mercurial treatment was continued, with similar, but less copious motions; no effect on the gums. She died on the 4th of October, somewhat suddenly.

Autopsy. — Pia mater congested; brain normal, except that it was firmer and drier than usual.

Extensive *engouement* of both lungs, first stage of pneumonia; heart normal.

The external surface of the peritoneum, the muscles being dissected from it, was red, and covered with apparent granulations secreting pus.

Much pus in the cavity of the abdomen. The peritoneal coat of the intestines was normal, except that slight and delicate membranes partially connected some of the convolutions.

The extent to which inflammation of thoracic and abdominal viscera, and hypertrophy of brain, had proceeded in this case, compared with the symptoms furnished during life, is remarkable. The mental and some of the physical symptoms resemble those of another case, which I will relate.

Eliza Gyon, aged 11, was admitted into my female ward, in the Infirmary, Oct. 29, 1842. She had been previously in the surgeons' ward, under strumous ophthalmia. She was then taken with the ordinary symptoms of fever, and transferred to the medical wards. She made no complaint of pain, nor did she seem to suffer any; lay straight

in bed on her side or on her back, and except some heat of skin and the inflammatory state of her eyes, exhibited no morbid physical symptoms. I understood that she had been perverse in the surgeons' ward, and this she seemed to manifest in the highest degree, refusing to give any information, and to do anything that she was desired to do, except eating and drinking. She repeatedly beat a little girl who, for a short time, was placed in the same bed with her; when not scolding, she was apparently inattentive and sulky. After a few days the heat of skin increased, and her mouth became much encrusted, as in fever. For the last four days of her life, the visage also had the character of severe febrile illness, but her fulness of person did not diminish. The bowels were regular, motions loose. Throughout this illness she took Hydrarg. Chlorid. grs. ij. 6tis., which were easily given her in food. She died on the 26th of December.

Autopsy. — The brain and thoracic viscera were healthy, cadaveric congestion (apparently) of the lungs.

On opening the abdomen, though only twenty-eight hours had elapsed since death, we noticed commencing putrefaction in the peritoneum, both intestinal and abdominal. The pelvis contained six ounces of pus. False membranes covered a portion of the intestines. There was an ulcer in the ileum, near the cæcum, of the size of a half-penny, perforating both internal coats; another in the colon, of the size of a sixpence.

On making inquiry at the school of the workhouse respecting this girl, I found that although rather dull and stupid, she was considered peculiarly good-tempered. In her, therefore, the peevishness and ill temper, so strongly expressed during illness, were undoubtedly indicants of disease. The question is not yet sufficiently explored, what precise changes of moral character and intellect belong to different states of disease.

In both the above cases of peritonitis the insidious march of the disease is worthy of notice. The following case illustrates an equally insidious coming on of peritonitis, under *other* circumstances, and has an important bearing on the subject of paracentesis.

John Strutt, aged 11, admitted into the Infirmary, May 26, formerly a man of intemperate habits; had laboured under ascites for three weeks. Tall, thin, dark; apparently he has been of strong constitution. There is evident fluctuation in abdomen; oedema of the legs and thighs; he can lie straight; pulse sharp, not strong, 80; occasional sputa, mucous, somewhat reddened; urine very deep coloured, clear on being heated, acid, not albuminous; sound on percussion best under right clavicle; breathing vesicular, but with a loud snore. very rough and mucous.

crepitous under left clavicle; he makes about a pint and a half of urine per diem; complete pulsations of the heart about thirty in the minute; numerous small irregular pulsations intermediately; its place apparently pushed up; no bruit.

The treatment applied was, *Elaterii* gr. $\frac{1}{2}$ every second night for five or six doses, then intermitted, and the course in a few days resumed. Acupuncture of thighs and legs, attended with free discharge, which greatly relieved him; frequent small blisters under the clavicles. His diet was nutritious, and freely taken.

Finding that his strength and feelings had improved on this plan, but that after a time he became stationary, and then seemed rather to recede; also that diuretics (except *elaterium*) were of no avail in his case, on the 29th of July I directed paracentesis; twenty pints were removed. During the operation, the heart's action became regular and steady. He described himself as much relieved.

Sumat. *Misturæ Juniperi* C. $\frac{3}{4}$ ss.; *Potassa Acetat.* $\frac{3}{4}$ ss.; *Sp. Æther. Sulph.* C. 3ss. 6tis.

On the 30th, his visage had become rather contracted; his tongue dryish, though of good colour; he had coughed much during the night; no motion; little urine; no tenderness or distension of abdomen; much fluid continued to flow from the puncture; scrotum swelled and painful; restlessness.

Sumat. *Fil. Hydrarg. Chlorid.* grs. iv.; *Morphiæ Muriat.* grs. $\frac{1}{2}$ bis quotidie; *Ol. Ricini* $\frac{3}{4}$ ss. statim. *Perstet* in usu *Misturæ*.

Aug. 1.—This plan has answered; more urine; bowels freely open; he looks better; the breathing quiet; abdomen soft, not tender; discharge from puncture great; no cough complained of.

Perstet *Ol. Ricini*, $\frac{3}{4}$ ij.

2d.—Sinking; he died on the 3d; he had six ounces of gin allowed him for the last five days, having previously taken three ounces per diem; his diet one chop, one egg, with bread and milk.

He was examined on the 4th.

The contents of the cranium were healthy. Some fluid in the pericardium; heart small, perfectly healthy; the aorta and pulmonary artery had a strong red tinge, apparently from imbibition; his left lung extensively adherent to pleura, and much gorged with dark blood, but perfectly crepitant; no tubercles; right lung similarly gorged, but less so in degree; liver normal in size, of nutmeg colour externally; universally hob-nailed, hard, and of a mud colour throughout. Kidneys healthy, except that they were rather soft. Spleen healthy; coagulable

lymph extensively spread on the peritoneum, giving out numerous and slight membranes adherent to the intestines; no inflammatory or morbid character of the puncture made by the trocar, which was closing up.

It is to be observed in respect to the operation here performed; 1stly, that the deterioration which proceeded after it, had commenced in some degree before it; 2dly, that the congestive state of lungs was plainly a state requiring relief, such as only tapping could afford; for, 3dly, the state of the liver makes it improbable that diuretics and purgatives could have removed the ascites, these remedies (which had indeed been tried) requiring a more healthy state of the general system.

The pathology of the peritonitic symptoms is obscure. Neither tenderness nor tension of the abdomen existed while this state must be supposed to have been proceeding.

[To be continued.]

MEDICAL NOTES.

By JAMES B. THOMPSON, M.D.

(For the Medical Gazette.)

A YOUNG lad on board the convict ship the "Marquis of Hastings," during the voyage to Van Dieman's Land in 1842, laboured under a most obstinate bowel complaint, for which every known remedy was tried, and without any good effect. Previous to this lad having been embarked, he had been subjected to somewhat of a rigorous discipline in the Parkhurst Institution, Isle of Wight, and was rather insubordinate, for which he was kept on low diet for some time. None of the remedial measures tried during the voyage succeeding, on the ship's arrival in Hobart Town, after a four months' voyage, the lad was reduced to a very low and enfeebled state. There was a consultation of medical officers held, when it was discovered that this lad suffered from the presence of a stone in the bladder, and which was only detected by accident while making an examination per anum for a supposed disease of the rectum. This case shows the precaution requisite in the treatment of all cases. Here was a case where the lad's youth would lead one to suppose the pressure or irritation consequent upon stone would be least likely to produce the symptoms that presented themselves. It was agreed upon to

improve and restore the general health, which was much deranged, and prepare him for the operation of lithotomy.

A woman, on board the barque "Eagle," on the homeward-bound voyage by Cape Horn, South America, from Sydney, New South Wales, in 1843, and who was a soldier's wife, and a confirmed gin-drinker, was in the habit of taking two scruples of Dover's powder at night, which was equal to four grains of opium. It does not act as an astringent on the bowels, as one would expect, and only barely produces an ordinary degree of sleep, and if not given in this quantity a less dose has the effect of acting as a stimulant. In some cases opium has been observed to act as a purgative, and the pulvis antimonialis as a sedative. In regard to this woman's case, it may be necessary to state that her husband, who was a soldier in the 80th Regiment of Infantry, and servant to one of the officers in Sydney, shot himself a few months before, while engaged in attendance at the mess-room. This, no doubt, must have preyed upon the woman's mind, and in the absence of gin on board, necessitated her to have recourse to the next intoxicating agent then at her command, and was a constant patient and consumer of opium during the voyage to this country, which varies from four to four months and a half: we sailed on the 25th of February, and arrived at Gravesend on the 2d of July, 1843.

Serjeant Weston, æt. 36, of the 80th Regiment of Foot, who was invalided home from foreign service, having served abroad for the usual period of years, and had latterly laboured under phthisis pulmonalis, was comparatively well during the homeward voyage, and that, too, at the coldest part of the passage to the southward of New Zealand, and while off the Cape Horn and the Falkland Islands; but the day on which we approached the tropics, and got abreast of Monte Video and Buenos Ayres, he got gradually worse, and his respiration became hurried. The mucus accumulated so rapidly when in the recumbent position that it was found necessary to support him half erect in his berth; and whenever he slept, from his total inability to

get rid of the mucus, he swallowed some, generally towards morning, which invariably acted as a purgative. At this period, in April 1843, the days became very agreeable and warm, when approaching the coast of the Brazils off Rio de Janeiro, and it was painful to witness this poor man's anxiety to get his summer or light clothing in readiness; it showed the peculiarity very strongly to be witnessed in this class of patients as they approach their end. He got gradually indisposed for his usual diet, his respiration became much engaged, and he pined and wasted away, and died on the 9th of May off Pernambuco, within a few days' sail of the equator. It was remarkable in this man's case to observe the little inconvenience which he seemed to experience during our voyage in icy regions, in lat. 57° 20' S. and long. 69° 44' E. when the thermometer stood very low, and at freezing point. It was interesting to notice the leeches which I brought with me from Sydney—their movements in the bottle always denoting a change of temperature and weather; they always crawled to the top of the bottle on the approach of mild and agreeable weather; but were as sure to drop down and lie meshed together in an inactive or dormant state at the approach, and during the continuance, of stormy and cold weather. They showed indications of a change from eighteen to twenty-four hours before we could ourselves anticipate any. I found a little sugar added to the water a great improvement. The water need only be changed once a fortnight in cold regions, but oftener in warm or tropical climates, varying the quantity of water to the number and previous applications of your leeches: a little fine sand is very desirable, and seems to be liked by the leeches, and with it they are less apt to prey upon each other.

Some remarks on a soldier labouring under insanity in a modified degree.

J. McEllroy, æt. 35, unmarried, of a nervo-sanguineous temperament, was on board the "Kent" East Indiaman on her outward-bound passage, when she took fire and went down. He being one of the survivors, served as a soldier for thirteen years in the 28th regiment of foot; was for three years confined in the Paramatta Asylum,

near Sydney; was generally quiet during the passage, unless he smoked more than usual—which was often found to be the case, the people on board giving him the requisites—when he was sure to amuse them all by becoming more talkative, and used to speak of his marriage with the Empress of Russia, and of his being a Doctor of Divinity of Cambridge, and a Doctor of Medicine of some other university. He said he had several musical instruments in his sea-chest, together with a supply of fresh provisions; but the chief mate would not let him have his key or his chest. He often says his officer has entered into a conspiracy against him, and gave fifty pounds for the purpose of forwarding his base project of a vile conspiracy. He is more excitable during the early part of the day, while in the tropics, than at any other period; and became rather violent during the ship's detention in the port of Pernambuco for water and fresh provisions. For several days we had to put the strait waistcoat on him, owing to the mistaken kindness of some of his fellow soldiers in providing him with tobacco or spirits, which no surveillance, however cautious, can guard against whilst a ship is in port. In a few days after we sailed, and when the excitement of shore wore off, he assumed his ordinary tranquil mood, and was generally observed to be amusing himself in singing some favourite songs.

The treatment was merely attention to the bowels and regulating the dietary, not allowing any stimulants, occasional shower baths, and very little tobacco. The croton oil, in colocyath pills, was found to be the surest and best purgative, and, I think, well calculated for such cases as the foregoing. This medicine seems to determine from the head, where there may be an undue tendency to accelerated or quickened circulation. The salt-water shower baths seemed to have a very salutary effect. An agreeable and light amusement, of some sort likely to interest the patient, is very desirable, together with a quiet steady man to take charge of the invalid, whose judicious resolve and firmness go a great deal to assist the physician in the cure or alleviation of the worst features in the case of the patient.

We are apt to find similar instances

as the foregoing amongst our soldiers invalided home from service in tropical climates. Still more frequently we will find delirium tremens very prevalent. It is not uncommon thing to witness one, two, sometimes more, soldiers carried off the ground after or during a morning's drill—which, by the bye, is sometimes carried to excess at home and abroad; but much more objectionable and culpable in a warm climate, where men are less capable of enduring much fatigue or waste of physical power.

REMARKS ON CONICAL CORNEA.

To the Editor of the Medical Gazette.

SIR,

I HAVE just had the pleasure of reading, in the last number of the Dublin Journal of Medical Science, a very ingenious and learned article on "conical cornea," by Dr. Pickford. As the able writer has, very unintentionally no doubt, overlooked my views on the nature and treatment of that singular malady, and attributed to others suggestions in reference to treatment which are due to me, I trust you will permit me a short space for the purpose of explanation.

Dr. Pickford has referred to the opinion of Mr. Travers, "who ascribes the disease to a constitutional origin;" and to that of Dr. Mackenzie, who, in the various editions of his Treatise, says "it (conical cornea) is probably an effect of some faulty action of the nutrient vessels of the cornea:" but he has omitted to state that I have considered conical cornea to be "the result of a change effected in the cornea by the modifying and arranging powers of the absorbents."* (Vol. i. page 529.) The following quotation from the last number of the Dublin Journal comprises the opinions of Dr. Pickford respecting the pathology of the disease. "In conclusion, I may repeat that I believe conical cornea to depend

* Further extracts would needlessly lengthen this letter. It is sufficient to state that I considered the disease to be not corneitis; or aquo-capsulitis; or dropsy of the anterior chamber; but an affection of the lymphatic system of the cornea. The subject needs renewed inquiry, and further elaboration; but I believe the views laid down in my Treatise will be found to constitute the basis of a correct pathology.

upon some disturbance in the functions of the great sympathetic, spinal nerves, and par vagum: producing, through the medium of the lenticular ganglion and fifth pair of nerves, faulty action of the nutrient capillaries and absorbent vessels of the cornea itself." Thus it appears that the views of Dr. Pickford, respecting the pathology of this singular disease, are little else than an expansion of my own, which were in no respect theoretical or speculative, but founded, as the Doctor himself has shown, on the result of pathological examination.

On the subject of treatment it becomes necessary again to assert my claims to priority of suggestion.

"The late Mr. Tyrrell," says Dr. Pickford, "hit upon a very ingenious, though very inefficient expedient, for remedying the defective vision. It consists in altering the position of the pupil, and removing it from beneath the centre of the cornea, or that part which has its figure most changed, to near the margin, where the least change has occurred."

The suggestion in question was first made by me, and not by Mr. Tyrrell, as will appear from the following quotation:—"Where the point of the conical cornea has become opaque, and vision is thereby rendered much more obscure than it would otherwise be, it has been proposed to make an artificial pupil near to the margin of the cornea, which, it is said, will have two important advantages; namely, 1st, removing the pupil from the opaque part of the cornea; and 2d, allowing the light to be transmitted through the least convex part of that membrane*."

The suggestion occurred to me whilst finally considering the subject, as part of my treatise; and was first made known to my pupils and professional friends, and put forth in my work in a scrupulously cautious and unobtrusive form, because I had, as then, no opportunity of reducing the plan to practice, and was unwilling to speak with confidence and decision in reference to a new surgical operation, respecting which I had neither practical know-

ledge, nor the opinions of others to sustain my views. Mr. Tyrrell does not say the operation had not been previously suggested and practised. In short, throughout the whole of his treatise he gives little attention to the names of contemporary writers, his work being manifestly intended to convey to the profession his own course of practice; the result of his own extensive experience on the various subjects comprehended in his able and eminently practical work. A writer of this valuable class does not step aside to trace the progress of knowledge,—to point out the various advances made by different writers towards the establishment of existing opinions: he chiefly desires to communicate to the profession the mode in which he treats disease;—to make them acquainted with his own views of disease, and method of treating them.

I should be reluctant to conclude without calling the attention of your readers to the ably-reasoned views of Dr. Pickford on the pathology of conical cornea, which appear to me calculated to effect a greater advance towards its correct and successful treatment than has been hitherto accomplished by the united labour and research of all preceding writers.—I am, sir,

Your obedient servant,

RICHARD MIDDLEMORE,
Senior Surgeon to the Birmingham
Eye Infirmary.

Jan. 16, 1844.

CASE OF ADDITIONAL NIPPLE.

To the Editor of the Medical Gazette.

SIR,

I HAVE just had the opportunity of witnessing, in a patient of mine, the following remarkable case. Should you think it worthy of insertion in your valuable journal, it is very much at your service.—I am, sir,

Your obedient servant,

THOMAS H. H. DAVIES,
Surgeon.

Liverpool, Jan. 20th, 1844.

Monday, the 1st January, I was called to attend Mrs. C. in her confinement. She proceeded through the different stages in the natural way. The next day she found that her linen below the left breast was saturated with

* See my Treatise, vol. i. p. 538. The first volume, in which the maladies of the cornea are discussed, was printed in 1834; six years before the appearance of Mr. Tyrrell's work. Other surgeons may have previously recommended the plan of treatment advised by me, but I am not aware that they have done so.

milk. Her attention being directed to the cause, she discovered something like a nipple. Upon my arrival she mentioned the circumstance to me, and I found, just below the substance of the left breast, on the integument covering that side of the chest, a decided nipple, about one-third of the usual size. It had a distinct areola around it, and milk issued very freely from it. The most extraordinary fact is, that she had already given birth to four children, but never before detected this anomaly.

I requested my friend Mr. Batty, lecturer on midwifery, to see the case; and he stated that he had never met with such an instance, either in his private practice, or in the public institution to which he belongs.

REMARKS UPON THE EDUCATION OF ARMY SURGEONS.

To the Editor of the Medical Gazette.

SIR,

THE insertion of the inclosed remarks upon the Education of Army Surgeons, in your periodical, would greatly oblige,

Yours obediently,

AN ASSISTANT SURGEON.

January 10, 1844.

The medical department of the army is under great obligations to Sir George Ballingall for his suggestion to establish professorships of military surgery in London and Dublin. But to administer to the practical benefit of such institutions, several obstacles to the advancement of professional knowledge among the medical officers of the army must first be removed. This important body of men in the service of the public are labouring under disadvantages, not only detrimental to the welfare of that service, but injurious to the art they profess.

Before exposing what I hope will be viewed as not trifling bars to professional preeminence in the service, I shall be excused by premising that, peculiarly in the science of medicine, the difficulties of acquiring experience are almost insurmountable, and that our actual information does not increase, in any degree, in proportion to our experience. "The accumulation of materials frequently rather retards than promotes its progress. In other

sciences, although truth is not to be attained without a certain degree of laborious research, yet to those who are willing to bestow on it the requisite attention, it is for the most part attainable, or if it still eludes our grasp, we are at least sensible of the deficiency, and can generally ascertain the precise nature of the obstacle which impedes our progress. In the other sciences, when we enter upon an inquiry, or propose to ourselves any definite object for experiment or observation, we are able to say whether the result of our inquiry has been satisfactory, and whether the object in view has or has not been accomplished.

"But this is unfortunately not the case in medicine. There are certain peculiarities necessarily connected with the subject, which render it extremely difficult to appreciate the value of experiment and observation. In our experiments we are seldom able to ascertain with accuracy the previous nature of the body on which we operate, and in our observations we are seldom able to ascertain what is the exact cause of the effect which we witness."

The history of medicine in all its parts affords ample testimony of the truth of these remarks.

Seeing, then, how great is the difficulty of acquiring medical experience under the most favourable circumstances, it will not be considered officious to suggest the removal of all tangible obstacles, and the adoption of every means favourable to this end. And this is the more imperatively called for, when it is known that the opportunities of making decisive observations on the external causes of diseases are much more superior in the army and navy than in civil life; and that it is by the medical officers of fleets and armies, "who are perfectly informed of the whole circumstances of the organized bodies of men under their observation, and often see these circumstances suddenly altered, or have even the power of altering them at pleasure," that this sort of inquiry has been prosecuted. By facilitating and encouraging these inquiries, we might expect that the lessons to be drawn from them would prove of even greater importance to the future happiness of mankind than any which we can gather from the history or treatment of diseases.

Whilst endeavouring to expose the *institutionary* defects of our department, without laying myself open to the accusation of introducing novelties, I have to bring to mind that "a froward retention of custom is as turbulent a thing as an innovation."

In the exposition of our grievances, it must be told that the pay and allowances of the junior class of medical officers of the army are inadequate to keep up the character as well of the officer and the physician. The expenses of the table at a modern mess swallow up the greater part of the pay of the junior branches of medical officers; and to these are added other numerous outlays, necessary for the *credit* of the corps. So that they can but ill supply themselves with books and scientific instruments, and but just obtain admission to the libraries where the opportunity offers. There is no provision, like in the scientific corps of Engineers, made to ensure medical officers a proper supply of books, instruments, stationery, &c. or even allowance to convey them where they possess them. Not only is this the case, but we are doomed to see our military brethren enjoying allowances, which, from a corresponding position, we should expect might have been extended to ourselves. This is evident in the cases of paymasters, adjutants, and quartermasters of Depôts, and reserve battalions, in which situation assistant-surgeons are allowed—nothing!!

The severity of duty is proverbial in the tropics and many other stations; but, however severe, there is no remuneration. Often we look with jealousy upon the officers commanding companies being allowed in some stations two servants, and officers of the Commissariat "climate money," which, perhaps, would somewhat also contribute to the health and comfort of the poor assistant-surgeon, who is at the beck and call of all, at all periods of the sultry day and infectious night.

The most important topic I would wish to dwell on, however, is the difficulty of acquiring medical knowledge in the army. The obstacles to this are many and conspicuous. The difficulty of acquiring medical experience demands that greater facilities should be given to medical officers to keep pace with their brethren in civil life, much

less to cultivate the science of medicine in various climes.

The custom of keeping medical officers abroad so long, without giving them an opportunity of returning home, oftener leads to neglect of science, to apathy, and even disgust. The evil of this counterbalances the good produced in acquiring experience of local diseases by long residence, as the knowledge is always but imperfect, and even empirical; whereas, from the observations of men who have the advantage of better physiological and chemical knowledge (to be acquired only by frequent study), much more valuable results would accrue.

The custom of keeping medical officers abroad so long, and the habit of refusing them leave at home or abroad, prevents them acquiring knowledge, which is allowed to military officers, by permission to repair to the public schools, &c. "Men returning from protracted absence or foreign stations" are with difficulty able to procure leave to renovate their health, much less to renovate their professional knowledge. By keeping up his knowledge of chemistry, and other collateral sciences, the army surgeon may often turn his talents to great advantage in observing and experimentalizing upon the external causes of diseases. Inability to procure books and means of improvement will dispose a man's life to sink into comparative indolence, and his time to be employed only in the ordinary routine of hospital duties, which too often degenerate into common-place practices. Long residence in remote stations, and the almost prohibition of leave of absence, leads but to inaction and inglorious indolence.

The absence of emulating societies, too, is not a trifling obstacle to exertion. The establishment of a society among the medical officers of the army would elicit valuable information from its members.

To remove these serious evils, more leave of absence should be granted to army surgeons, to facilitate the acquisition of medical knowledge, as the science is so comprehensive as to require continual study.

The neglect of the medical officers of the army conduces to extinguish all effort and combination for success. General and principal medical officers

seldom, if ever, notice the services of the medical department of the army. Indeed, the marked neglect, and the species of superciliousness, not warrantable by any difference of station in society, and certainly not by better mental cultivation, shown by many military commanders towards the class of medical officers, is not so conducive to exalt the general, as it is to destroy self-respect, and to teach servility in a shy and young medical officer.

These few words but imperfectly expose real grievances, but perhaps may prove sufficient to those who are disposed to read them. The scheme of granting medical men more leave to study in the public schools, either at home or abroad, is sufficiently practicable. Those applying should, of course, be recommended by the Director-general at home, and principal medical officers abroad.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

Cataract, and its Treatment; comprising an easy Mode of Dividing the Cornea for its Extraction, and appropriate means for removing the different forms of that affection. By JOHN SCOTT, Senior Surgeon to the Royal London Ophthalmic Hospital, Surgeon to the London Hospital, &c. Churchill. 1843.

MR. SCOTT regards both the difficulty and the chief danger which attends the extraction of cataract as depending upon the force required in transfixing the cornea with the instruments generally used for that purpose. Spasm of the recti muscles is thus induced, by which the iris becomes compressed between the lens and the edge of the knife, giving rise to inflammation, and thus leading to the unfavourable result which too often follows. The author has invented a knife by which he states that the evil above alluded to may be avoided; and the main object of the little volume which lies before us is to introduce the new instrument to the profession.

Mr. Scott takes the opportunity of entering into a description of cataract, detailing the general symptoms, the

different forms, and their diagnosis. Into these subjects, however, we deem it unnecessary to follow him; but proceed to notice his observations regarding the treatment. The chief points to which, in this department, he refers, are the circumstances which preclude the propriety of removing the cataract by any operation; those in which an operation is proper; and, lastly, the different modes in which such operation may be performed, as adapted to different kinds of cataract.

Our author is of opinion that the operation is seldom proper to be performed on an eye which retains a useful degree of vision, the patient being very apt, should it fail, to complain of being worse off than he was before. Thus, he remarks, applies more especially to cases of congenital cataract, in which only the centre of its lens is opaque, and the patient thus retains pretty good vision through the transparent circumference; so that, by means of belladonna, he may retain a useful amount of vision for years; but this he of course loses if the operation should fail.

Neither does our author regard it as judicious to operate till the other eye be so much impaired as to convince the patient that it must soon be entirely lost, as he is prone to attribute the loss of the second eye to what has been done to the first.

The cataract, however, being now considerably advanced in the previously sound eye, no farther delay ought to be encouraged. Mr. Scott thinks choice should be made of warm weather, as, in old persons especially, the section of the cornea then heals so much better than it does during cold; so that operating in winter much diminishes the chance of success. He is also much against operating on both eyes at once.

The modes of operating for the removal of cataract are described under the following heads:—

“1st. The making a section of the cornea, through which it is removed altogether from the eye, and which is called the operation of extraction.

“2d. The depressing the lens below the axis of vision, and leaving it imbedded in the vitreous humour, which is called the operation of depression or reclinatio.

"3d. The opening out of the texture of the lens, and exposing it to the solvent power of the aqueous humour, which is called the operation by solution or absorption."

In performing the first of these—extraction, it has been frequently advised that the pupil be previously dilated by means of belladonna; but Mr. Scott sees no advantage to be gained by this under ordinary circumstances.

The operation may be regarded as consisting of three parts—making a section of half the circumference of the cornea, lacerating the anterior capsule, and removing the opaque lens.

The section of the cornea may be made in various ways: either transversely downwards or upwards, or obliquely downwards and outwards. Mr. Scott always prefers the transverse upper section, as he is then able to steady the globe of the eye, and himself control the upper lid, while by pressing with the back of the knife, he prevents the eye from being turned upwards. The flap of the cornea is little liable to be disturbed, and prolapse of the iris is thus guarded against. The only circumstance under which our author ever practises the lower section is where the brow is so prominent as to forbid the other, a circumstance which very rarely occurs. He sees no advantage in covering up the other eye, as is usually done: but directs the patient to fix it on the light before him, which tends to steady the other eye likewise.

The instruments to be employed are, the cornea knife, for dividing that part; a blunt-pointed curved knife, for enlarging the section if necessary; a curette, for lacerating the capsule; a sharp-pointed hook, for removing the lens if the fluid state of the vitreous humour should prevent its removal by pressure; and a pair of Maunoir's scissors, in case the iris should be wounded in the section of the cornea, to divide the intermediate fibres between such aperture and the pupil.

The cornea knife (and this is the chief point with Mr. Scott) must increase both in width and thickness from the point to the heel, that it may completely fill up the section which it makes, and thus prevent the aqueous humour from escaping. It must also be of such width as to divide one-half the circumference of the cornea, as

the lens nearly equals the cornea in diameter. We think it best, however, here to let Mr. Scott speak for himself; and subjoin a quotation embodying the chief points regarding the form of knife which he proposes.

"The objects I propose to attain in the construction of the knife are—

"1st. That it shall be of sufficient length to traverse completely the anterior chamber, and divide the nasal margin of the cornea.

"2d. That it shall increase in width and in thickness from point to heel enough only to prevent the escape of the aqueous humour in its transit across the anterior chamber, but that its width shall have no reference to the dimensions of the section that is to be made, as that circumstance, I conceive, has occasioned all the difficulty of its introduction, and the chief danger of the operation.

"3d. That it shall be of such a shape and figure, that when introduced in the middle of the temporal margin of the cornea and carried across the anterior chamber, it shall readily puncture the nasal side of that membrane; and when placed in this situation, the cutting edge shall be so far beyond the pupillary margin of the iris, and opposed to so large a portion of its anterior surface, as will prevent its escape beneath the edge of the knife to endanger its division in making the section of the cornea.

"4th. That when the section of the cornea is thus about to be made, the edge of the knife shall be opposed only to the margin of the section on either side, and not to any extensive portion of its internal surface, whereby its division would be attended with difficulty, as is the case in using Beer's knife.

In order to attain these objects, the knife must describe a portion of a circle of larger diameter than that of the cornea; and after having tried a vast variety of shapes and sizes, the one I now propose seems to me to fulfil the foregoing indications the most effectually. At first I used a much narrower and finer knife; but I found that, in introducing a cutting instrument of such a length, the aqueous humour was liable to escape unless it increased more rapidly both in width and in thickness. I have also tried one wider at the heel; but in that

case greater force is required for its introduction, which is not counterbalanced by any commensurate advantage in completing the section, unless the cornea be of unusually large dimensions.

"The back of the knife describes a sixth part of the circumference of a circle, the radius of which is ten lines. The chord of the arc formed by the back of the knife is, of course, also ten lines in length, being equal to the radius of that circle; it is therefore greater by four lines than the diameter of the cornea, and the blade is consequently quite long enough to complete the section of that membrane without difficulty. The knife is two lines in width at the heel, whence it gradually tapers to the point; it also increases uniformly in thickness, as well as in width, from point to heel, so as to occupy completely the aperture it makes in the cornea, for the purpose of preventing the escape of the aqueous humour."

"In making the upper section of the cornea with this knife, it is to be held in the usual manner, between the thumb and two fore fingers, the two other fingers resting on the patient's cheek, and the handle of the knife inclined slightly towards the side of the face, while the point punctures the cornea on its temporal margin; the handle of the knife is then to be brought upwards with a sweep as the blade traverses the anterior chamber: in doing this, great care must be taken to press firmly downwards with the back of the instrument, so that the wound may not be unnecessarily enlarged by its cutting edge. This being accomplished, the point of the knife will have reached the nasal canthus of the orbit, and its cutting edge will be so far beyond the pupillary margin of the iris that it cannot be readily divided in completing the section of the cornea. The point of the knife is then to be carried upwards, the handle being slightly inclined in the opposite direction. The section of the cornea on its nasal side will now be complete, a small portion at the upper and outer part only remaining to be divided; and this is readily done in the withdrawing of the instrument.

"In this way, the cornea being transfixed by an instrument of such a size only as will prevent the escape of

the aqueous humour, no unnecessary force is employed, either in accomplishing this object or in preventing the eye from rolling inward. The section is completed, not by thrusting a wedge-shaped knife through the anterior chamber, the cutting edge of which divides the circumference of the cornea, only by the force with which its back is pressed against the opposite side of the section, but by an instrument that accomplishes the division of the membrane independently of any such pressure on its back. No unnecessary force is therefore had recourse to, and consequently spasm of the muscles of the globe is much less liable to occur; the aqueous humour is much less likely to escape; and if it should do so, the shape of the knife and its position in the anterior chamber are such, that the iris can scarcely fall forward before its edge; and even if this should be the case, it will much more readily recede behind it, under the slightest pressure of the finger on the cornea.

"In addition to these advantages, it may be observed, that the danger of bruising the iris, by the forcible compression of it against the knife, when spasmodic action of the muscles of the globe occurs, is also avoided, and the consequent chronic inflammation of that structure, that is so liable to be produced from this cause, is likewise obviated."

It is very customary to bleed patients before performing the operation of cataract, with a view of diminishing the risk of inflammation. Mr. Scott does not find this necessary, and mentions, in illustration, that of the last fifty cases of extraction, taken in succession, which he has had at the Ophthalmic Hospital, no blood-letting has been required either before or after the operation. Every precaution, however, is taken to have the patients in a favourable condition, by attention to diet and regimen, and to avoid any degree of violence during the operation itself.

Various other points of interest connected with the subject of cataract are alluded to by Mr. Scott, in the manner of one familiar with the subject of which he treats. We have, however, sufficiently entered upon the chief object of the little volume before us, which we recommend to our readers as

of small price and modest aspect, containing much useful information within a very limited space.

A Practical Treatise on Organic Disease of the Uterus: being the Prize Essay to which the Medical Society of London awarded the Fothergillian Gold Medal for 1843. By JOHN C. W. LEVER, M.D. &c. 1843. Svo. pp. 240.

EXCLUSIVELY of an introduction containing an account of methods of examination, and the general symptoms of organic disease, Dr. Lever's work is divided into three parts. The first treats of inflammation of the uterus; the second of polypus uteri, fibrous tumors of the uterus, &c.; the third of malignant diseases, namely, cauliflower excrescence, corroding ulcer, melanosis, and cancer.

Dr. Lever has seen inflammation of the uterus produced by the *secale cornutum*.

"In some cases the inflammation is of a sub-acute kind from the first, and especially in those cases where the *secale cornutum* has been given improperly. I had under my care five females attended by the same individual, to all of whom he had given the *secale*, and who were affected by the same symptoms: central pains, increased upon assuming the erect posture, by defecation, and micturition; tenderness above the pubes; thick white discharge, at times streaked with blood. There was considerable constitutional irritation, marked by a quick small pulse; heat of surface, alternating with chills; coated furred tongue; scanty, high-coloured urine; thirst; loss of appetite, &c. On vaginal examination, the uterus was found to be enlarged, the os tumid and tender, and great pain was excited by pressing with the finger upon the cervix." (p. 43-44.)

The treatment consists in cupping, leeching, anodyne injections, alterative aperients, saline medicines, and abstinence from the husband's bed. "After the active symptoms are subdued," says our author, "the patient will derive great benefit from the use of tepid salt water baths, and a residence by the sea-side will hasten the recovery." But may not the hip-bath at 95° or 96° be used with advantage, as soon as the

first set of leech-bites have begun to heal?

Many of the statistical facts collected by the author are interesting. It would appear that functional diseases of the uterus are to organic ones as 2 to 1.

Dr. Lever's work is sensible and judicious; it is the production of a man who has seen much practice, and shows an unwearied industry, which must of itself produce considerable fruit.

MEDICAL GAZETTE.

Friday, January 26, 1844.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medice tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

FRENCH AND ENGLISH PRACTICE.

To pass a just judgment on foreign nations, and foreign habits, is proverbially difficult, if not impossible. The traveller sees every thing through the mists which haste and prejudice spread before him. His ear falsifies the sounds which reach it; his eye distorts the images which impinge upon it; and with every disposition to be honest, he puts down in his note-book what the polite Houshynms called "the thing which is not." In some instances (a minority, indeed,) his retina retains only the most gorgeous rays, and, like a sovereign on a progress, he sees nothing but festive tables, and gala dresses.

Hence, it is a subject of congratulation to the lover of truth when the traveller becomes a resident, and, instead of writing a three months' tour through a large empire, takes the trouble to ascertain facts, and weigh opposite statements.

Dr. Higgins, an English physician who has resided fifteen years in France, has addressed a letter to the *Gazette Médicale*, which is entitled, *Sur l'usage des tisanes en France*, but which, in fact, touches on some of the chief points

of difference between French and English practice; and our readers will not be sorry to hear the testimony of so enlightened a witness. First, he deposes touching ptisans. Now a ptisan, according to Dr. Johnson, is "a medical drink made of barley, decocted with raisins and liquorice;" while a French *tisane* may be made either of rice*, grits, gum Arabic, prunes, jujubes, dates, tamarinds, asparagus-roots, quassia, valerian, roses, violets, red poppies, or a host of other substances. In fact, the codex alone contains nearly fifty *tisanes*; and many more are, no doubt, known in private practice.

In France, whether a disease is acute or chronic, a *tisane* is always prescribed, and its selection is considered a matter of the highest importance, for it is supposed to be a decided therapeutic agent, not a mere beverage, or diluent. Hence the choice of the *tisane* is much criticised, and physicians have been dismissed in pursuance of an unfavourable sentence passed by a female conclave anent the chapter of *tisanes*.

It seems that in France they reckon up four kinds of this beverage, namely, the diaphoretic, the diuretic, the diluent, and the aperient. The first are evidently indicated in certain cases; but Dr. Higgins thinks that the diuretic ones are even more useful in the diseases where *they* are applicable; for while perspiration can be excited by other means, these remedies alone act on the kidneys. So far Dr. Higgins. On looking, however, into the long list of official *tisanes*, we can recognize but one diuretic among them, namely, the infusion of asparagus roots; and though others may probably be in use, it surely cannot be necessary that the active principle should always be administered in this expanded form. The

usefulness of the third class, or diluents, is obvious; these, and the fourth class, or aperient *tisanes*, are much used and abused in France.

Indigestion, says our Anglo-Gallic brother, is more common than all other diseases put together. It is needless to dilate on its symptoms, such as constipation (or, sometimes, diarrhoea), fetid breath, pasty taste in the mouth, disordered secretion of the liver, and so forth.

Now, supposing these symptoms to proceed from inflammation of any abdominal organ, the first point of the treatment, namely depletion, would be the same in France and England, but probably there would be more venesection on this side the channel. Afterwards, however, there would be a divergence in practice. In France the physician would content himself with prescribing diluent *tisanes* for several days, and then proceed to aperient ones. In England the physician would press onwards more rapidly, and not putting his trust in any *tisane*, would give purgatives, and often follow them up by active diaphoretics.

Which of these methods is the best? Dr. Higgins thinks that the answer depends on the medical constitution, that is, on the reigning type of disease.

When this is inflammatory, as it was when the doctrines of Broussais were in vogue, the French practice is preferable; while the English system is best amid the present forms of disease.

At the commencement of the present century humoral diseases prevailed, or, in other words, the secretions were much disordered; and it was then that Hamilton wrote the famous treatise which has had so strong and long an influence on English practice. British physicians, indeed, found purgatives so efficacious, that when, some years afterwards, Broussais pointed out the arrival of the in-

* *Sume hoc ptisanarium oryxæ*, says Horace. Sat. Lib. 2. iii. 155.

inflammatory type, many were unwilling to adopt the new treatment, so efficacious had they found the old one; and thus the theories of Broussais did not meet with the attention which they deserved in England. In France, on the contrary, it was much more favourably received; young physicians adopted it almost blindfold, and their seniors found much in it to modify their former practice. But now another change has taken place in the type of disease; for the inflammatory constitution has been succeeded by its old predecessor, the humoral or catarrhal type. Hence the English, by persevering in the Hamiltonian system, have come right again, "and thus the whirligig of time brings about its revenges."

Gastritis and gastro-enteritis are said to be far rarer than they were fifteen or twenty years ago, and, when they do occur, but seldom require the abstraction of blood; while cases of disordered stomach, with secretions altered in quality or quantity, are of daily occurrence.

Let us take a case of the kind, says Dr. Higgins, and see how it would be treated in England and in France.

A patient suffering from indigestion complains of want of appetite, constipation, weight at the epigastrium, bad taste in his mouth, and head-ache; sometimes, also, of colic, nausea, pain in different parts of the body, &c.; the tongue is foul, if not all over, at least towards the root. In England, the physician would prescribe for this patient two pills consisting of rhubarb, calomel, and aromatic powder, to be taken at bed-time, and a black draught the next morning; or else a glass of Seidlitz water, or an ounce of castor oil; with barley water and a cup of weak tea for drink, and a little broth for dinner. The next day the patient is well. Why does the English phy-

sician pursue this plan of treatment? Because he considers the symptoms to proceed from the fulness of the intestinal canal, clogging the digestive functions, and reacting upon the secretions. Now Broussais, or his disciples, would look on such an indisposition as the result of a gastro-enteritis, and would treat it as such. They would prescribe leeches, cataplasms, emollient drinks, low diet, and perhaps a few clysters; and in eight or ten days they would venture on a gentle purgative. In Paris, indeed, and the greater towns of France, there are few physicians so timid at the present day; but in the country the use of *tisanes* and the fear of purgatives are excessive. Even in Paris, where the treatment is more like English practice, *tisanes* would be used at the commencement of such a case, and the physician would end, where we should begin, with the employment of purgatives. The consequence is, that the English patient is cured in one quarter of the time of the French one; and this from practitioners persisting in Broussais' method after the type of disease on which it was founded has disappeared. Meantime the *sommités médicales* of France have for some years begun to deviate from the principles of Broussais, and recognize the advent of a new reign, without being able entirely to throw off their old prejudices.

Again, if we suppose the case, instead of mere disorder of the digestive organs, to be a genuine gastritis, or gastro-enteritis, the antiphlogistic system is to be pursued, but without the use of aperients, until the acute symptoms have given way. But if we attempt to fix the point when purgatives may be administered, opinions on the two sides of the channel diverge. The French physician wishes to temporise, and is afraid that the irritation caused by purgatives will force him to recur to bleed-

ing, though the patient is already weak from previous depletion. The English physician, knowing the immense relief derived from opening the bowels, is impatient to administer a cathartic.

In such cases, the doctrines of Broussais have, no doubt, had their influence in England, though less, we apprehend, than Dr. Higgins supposes; for few practitioners with us would easily find a gastritis or gastro-enteritis so acute as to prevent the occasional exhibition of a dose of castor oil; we should all acknowledge the possibility of such a case, but be loth to see that it had occurred.

This, perhaps, is an error on one side. French physicians stray in the other direction, and are so afraid of inflammation, that the slightest tenderness on pressure contra-indicates, with them, the use of cathartics, even though there is neither thirst, nor a white tongue, nor a quick pulse. They forget the natural tolerance of the mucous membrane of the stomach and bowels.

It bears, says Dr. Higgins, truffles and lobster, tunny, *liqueurs*, and strong wines, yet they shrink from a few grains of rhubarb and scammony. To this we suppose that the French doctors would answer that they never prescribe *thon mariné, dindon aux truffes*, or maraschino, in cases of gastritis. Nevertheless, we agree with Dr. Higgins that the tolerance of the stomach is great, and is generally far from being outraged by cathartics. Hippocrates, if we recollect aright, compares it somewhere to a leather bag.

As to calomel, it is supposed in France to constitute almost the whole pharmacopœia of English physicians; it is supposed also to be given in enormous doses, and uncombined. We ourselves think that a *juste milieu* is wanting between the excessive use of calomel in England (for excessive it still is, in spite of the reform which

Dr. Higgins alleges) and the strange neglect of it in France.

Dr. Higgins is of opinion that the doses of medicines should generally be one third less in France than in England; but he utterly rejects the theory that the treatment of disease ought to be radically different.

He believes this theory to be founded on the old prejudices which prevailed in each country respecting the inhabitants of the other one.

In England it was believed that there were no large men in France; that they lived on soups and salads, and used no drugs but *tisanes* and *clysters*!

In France it was believed that the English ate nothing but potatoes and roast beef half raw, and swallowed no drug but calomel!

LECTURE
ON
ABSCESS AND FISTULA CONNECTED
WITH THE RECTUM,

*Delivered in the Theatre of St. George's
Hospital, January 10, 1844,*

BY SIR B. C. BRODIE, BART.

[The subject continued from the former lecture.]

I CONCLUDED the last lecture with speaking to you of the mode of performing the operation for *fistula in ano*, where that fistula is of the simplest kind; but I now come to consider what is to be done in cases of fistula where there is some kind of complication.

Sometimes the external orifice is at a considerable distance from the verge of the anus—perhaps two or three inches: it may be even situated near the middle of the buttock. You may then, if you please, perform the operation in the manner which I have already described—that is, by introducing the probe at the external orifice, then along the fistula into the rectum, feeling for the end of the probe in the bowel, passing it into the bowel through the internal orifice just above the sphincter muscle, and then dividing the whole with the knife-edged scissors, or some other cutting instrument. But this is a very serious operation, on account of the extent of the parts to be divided: and a very painful one. There may be considerable hæmorrhage: and, at any rate, there must be a very large surface to

be healed. And the fact is, that this extensive division of parts is not at all necessary, and may be avoided if you proceed in the following manner. Introduce the probe-director, as I may call it, into the gut, through the fistula, in the way which I have already described; then feel for the instrument at some little distance, say three-quarters of an inch, from the anus, and at this point, with a lancet or a double-edged scalpel, make an opening through the skin and adipose substance leading down to the groove of the director; then take out the probe-director, and introduce it into the orifice which you have made, as if the latter were really the external orifice of the fistula; from thence pass it into the rectum, finishing the operation by the division of the parts over the director in the usual manner. Thus you accomplish all that is wanted with a very small incision, laying open the internal extremity of the fistula, and leave the external extremity alone. The fistula, as I have already explained, is prevented from healing by some of the *faeces* becoming infiltrated into it. But for this the whole sinus would heal at once. The external extremity of the fistula, it is true, in this mode of performing the operation, remains undivided; but the *faeces* cannot find their way into it, and in a very short time it heals spontaneously; while the other extremity is dressed and healed from the bottom as in ordinary cases.

You will meet with not a few cases in which matter has burrowed and made many sinuses in the vicinity of the rectum, some in one direction and some in another. Sometimes these complicated sinuses are confined to one side of the gut, and at other times they occur on both sides. Before you proceed to an operation in a case of this kind you must examine the parts very carefully, and three or four examinations may be required before you can make out the exact state of the case sufficiently to guide you in the operation. Introduce the fore finger of the left hand into the gut; then endeavour, with the probe introduced into the different sinuses, to ascertain whether there be only one internal communication with the gut, or whether there be more. Very often, where there are several sinuses external to the gut, communicating with one another, there is only one original sinus opening into the bowel; but at other times there are two such communications, or even more. Whatever sinuses there are communicating with the bowel, they must be divided; but as to those which do not open into it, it very probably may be quite unnecessary to interfere with them. If you make the original sinus an open sore, the *faeces* will not enter the secondary sinuses, and there will be nothing to prevent them

from healing. The only exceptions to this rule of practice are those cases in which the matter is not freely discharged from the secondary sinuses, but lies and lodges in them: they may then require to be laid open to prevent such accumulation.

I have told you that if you examine carefully, and look for the internal orifice of the fistula in the right place, just immediately above the sphincter muscle, you will scarcely ever fail to find it. If you do not succeed the first time, you will the second or third. But sometimes the opening is so small, and the sinus takes such a circuitous course, that you may examine the patient two or three times without detecting it. This, I say, will happen sometimes—not often; and what is then to be done? Perhaps, if you were to delay the operation still longer, you might discover the orifice at last; but the patient gets uneasy and impatient at the cure not being completed, and is anxious for something to be done. You must then do what Mr. Pott recommends as a general practice; you must make an artificial opening into the gut. You may use the probe director or a common probe-pointed bistoury, as you please. With the fore finger of one hand in the rectum to direct you, you must cause the point of the instrument, whichever you employ, to perforate the membranes of the gut some way above the sphincter muscle, and then divide the sinus. But this is a very unsatisfactory way of doing the operation, after all; and you may be assured that, if you make an artificial opening into the gut, and do not find the real and original opening, it is doubtful whether you will make a cure. In many cases, at least, you will be plagued afterwards. You have made an artificial opening, but the original opening remains; and although you go on dressing the sore, there is a little infiltration of *faeces* and mucus into it that prevents the completion of the healing process.

When you have to make an artificial opening in the way which I have just mentioned, I advise you to proceed still further. Having laid the fistula open into the gut, take a straight probe-pointed bistoury, introduce it into the rectum, turn the cutting edge outward, and divide the sphincter muscle so as to set it completely at liberty. No large division of parts is necessary for this purpose; and this being done, you will seldom have any trouble in the healing of the wound afterwards. I say this is better than merely laying open the sinus into the gut, where you cannot find the internal orifice; but there are objections to this more complicated operation which there are not in the other; because there is more bleeding; because you give your patients more pain, and there is a larger wound to

heal. The bleeding, however, from the division of the sphincter muscle, I may take this opportunity of mentioning, however considerable at the moment, is never dangerous. It is completely within reach and under control. You may probably see the vessel that is divided, and secure it by ligature; but if not, a dossil of lint, dipped in a styptic lotion, laid on the part, and retained there by the finger of an assistant for half an hour, will always stop it.

I told you that, in some cases, a fistula has no external orifice, and I described two classes of cases of this description. In one of these there is a small internal opening; and the fæces having penetrated into the cellular membrane external to the gut, an abscess has been formed which has burst into the rectum by another opening above the original one. In this case, by pressing externally, you may generally discover where the matter is lodged. One day the abscess is empty; another it is full. Take the opportunity, when the contents of the abscess are accumulated, so that you may feel the matter through the integuments, to make a puncture with a lancet, and having done so you reduce the blind fistula (as it is called) into the state of a common fistula, with this difference—that there are two internal openings instead of a single one. The further steps of the operation are the same as in ordinary cases, except that you must, if possible, discover both the internal openings, and let them both be included in the incision of the gut. Then I stated that there is another case, in which there is an ulcerated cavity in the neighbourhood of the rectum, having no external communication; and where the orifice in the bowel, instead of being, as it is in common cases, not much bigger than a pin-hole, is large enough to admit the end of the little finger into a cavity by the side of the gut. Here you are to proceed in the following manner. The broad internal opening is always close to the sphincter muscle, and almost, if not quite, always at the posterior part, just opposite the point of the *os coccygis*. You must employ a probe bent in the manner I now show you, and introduce it into the rectum with the bent point towards the abscess. You then draw it down; and as you do so the point will enter the ulcerated cavity, so that it may be felt under the skin. You may now procure an external opening by puncturing the skin with a lancet so as to reach the point of the probe, after which the fistula is to be laid open in the usual manner. [The mode of performing these operations was illustrated by a diagram.]

There is another form of fistula of the rectum that requires especial notice. I do not know that I can better explain what

I mean than by relating briefly the following case. A middle-aged lady had an abscess form in the front of the rectum. It was formed, I imagine, from ulceration of the gut in the usual manner. The abscess burst just by the posterior margin of the vagina. It appeared like a common fistula, and she consulted a surgeon, who inadvertently treated it as such, and laid it open into the gut. But what was the consequence? He had divided both the *sphincter ani* and the *sphincter vaginæ* muscles. The wound never perfectly healed; she was in the condition of a patient with lacerated perineum, and all the rest of her life was liable to an involuntary discharge of fæces, of course making her unfit for society, and in every way miserable. I saw this case some twenty-five years ago, and it has been a lesson to me, as you may suppose, ever since. It is not very often that abscesses of the rectum do burst in this situation; I have only seen a few examples of it; but the case I have mentioned was sufficient to satisfy me that some peculiar mode of treatment was necessary. How is such a case to be treated? I have seen this kind of fistula two or three times where I have had no opportunity of following up the management of the case; but rather more than a year ago a case occurred in which I was called upon to do so. I merely made a free division of the sphincter muscle, cutting across its fibres so as to set it completely at liberty. I dressed the wound to the bottom with lint. The sphincter in a great degree lost its power of retaining the fæces, and it was a long time before its functions were resumed. That was what I desired. The discharge from the fistula immediately became very much diminished, and it continued gradually to diminish further. When I last saw the patient, which was about two months ago, there was no discharge at all; and it appeared to me that the fistula was soundly healed. Why is it that the fæces get readily infiltrated into the internal orifice of the fistula? Because there is an obstruction to their exit occasioned by the sphincter muscle. By dividing the sphincter muscle you take away that obstruction, and the fæces escape so easily from the anus that they do not pass into the fistula. I must say, however, that I was led to adopt this plan of treatment partly from the well-known success of it in cases of simple ulcer of the rectum, and partly from what had been done in a case of another kind by another surgeon. Mr. Copeland says that he was consulted by a lady who had an ulcerated opening between the rectum and the vagina: that he divided the sphincter muscle, and set it completely at liberty: and that after some time the recto-vaginal communication was closed, and at last firmly cicatrised.

Having told you how these fistulous sinuses are to be laid open, let me say a few words about the dressing. If the operation be done in a proper manner, very little dressing is in general required, and indeed it is only a very narrow sore that is to be dressed at all. Do not cram the parts full of lint; all that you want is, to lay a little lint between the edges, to prevent them adhering prematurely. If the healing process goes on slowly, it may be useful to stimulate the surface by a dressing of the citrine, or red precipitate ointment. When the parts are fairly granulating, you may hasten the cicatrisation (that is, the formation of new skin) by touching the surface lightly with the nitrate of silver. It is seldom necessary, except in complicated cases, to continue the dressings for any considerable length of time; a few days are often quite sufficient. Indeed, after the cut edges are skinned over, the dressing is hardly necessary, and you may save both yourself and the patient a good deal of trouble by merely touching the surface of the sore every other day with the nitrate of silver, and using no dressing at all.

Let the cut edges be fairly skinned over, and the rest of the sore will cicatrise sooner without the dressing than with it. If you cram the part full of lint you give the patient a good deal of pain, and I am sure that it sometimes happens that, being obstructed by the pressure of the lint, the matter does not easily escape, but burrows in the cellular membrane, and makes fresh sinuses.

Abscesses sometimes occur about the rectum, which may be confounded with that particular disease which I have just described; and I shall say a few words on these cases, in order that you may distinguish them.

Suppuration sometimes takes place in an external pile. An external pile inflames; after a few days you are sent for to the patient, and you find an abscess just on the point of bursting. You open it, and let out perhaps a tea-spoonful, or more, of matter; but if you pass in your probe it will not penetrate by the side of the gut, and perhaps not further than half an inch. This sort of abscess is often very painful, and otherwise troublesome. The patient can hardly bear to go to the water-closet, and he has pain and difficulty in throwing out the last drops of urine. The treatment is very simple: for you may cure it at once radically by cutting off the external pile, abscess and all, with a pair of curved scissors. The same thing will sometimes happen with an internal pile. A patient has a pile of this description, which has protruded externally. Inflammation takes place in it, an abscess forms and bursts, and you may pass the probe into the abscess, and into the centre

of the pile. Here, also, if the pile is small enough, the best way is to snip it off with a pair of scissors; or, if it be not small, tie a silk thread round its base, and destroy it by ligature.

I may mention to you a blunder which, in these last-mentioned cases, you will be liable to make if you are not on your guard against it. When you introduce the probe into an abscess formed in an internal pile, the probe very easily breaks down the slender wall of the abscess, and runs into the cellular tissue under the mucous membrane of the gut; and the cellular tissue gives so little resistance to the probe that it will pass any number of inches between the mucous membrane and the muscular tunic as easily as if it had penetrated into an actual cavity. I remember a case many years ago, where a surgeon, who was at that time of great eminence in this town, not being aware of this circumstance, laid open what he thought was a sinus two or three inches into the rectum. I am satisfied, from what I remember of the case, and what I have seen since, that it was an abscess formed in an internal pile, and that what he supposed to be a sinus was neither more nor less than a space he had made himself by running the probe into the loose cellular texture.

It is, I suppose, from the analogy of abscesses and fistulae of the rectum, and from it being generally necessary that these should be laid completely open into the rectum, that some surgeons have been led to think that the same kind of operation is necessary for all kinds of fistulous sinuses wherever they are situated. I can remember the time when some very good surgeons in this town used to think that what is called fistula in perineo was to be treated in this manner. There can be no greater mistake. Fistula in perineo is formed in the same way as the fistula in ano, except that the one communicates with the urethra behind a stricture; and the other with the rectum above the sphincter muscle. A fistula in perineo is prevented from healing by some of the urine passing into it from the urethra. But the laying it open does no good, for it does not remove the cause which produced it. But this object may be attained simply by dilating the stricture, and in 19 cases out of 20 that is all you have to do. Generally by the time the stricture is dilated, the urine flowing more readily by the passage forward than it does through the ulcerated opening, it will not pass into the latter at all, and the fistula is healed by the time the stricture is dilated. If it should not be completely healed, you have only to keep the stricture dilated for a considerable time by introducing an instrument every day, or every other

day, and the sinus in the perineum will heal at last. If it be a large opening it may take some months to heal, but still it heals sooner or later. There is only one kind of case in which it is necessary to lay open a fistula of this kind, and that is where it is so circumstanced that neither the urine which enters it, nor the pus which it secretes, can freely escape, and a free incision is not only useful, but necessary.

There are fistulous sinuses which exist in the groin in connection with disease in the inguinal glands, and I can also remember the time when very good surgeons supposed that they required to be laid open like *fistula in ano*. It is true that if matter lodges in them, and cannot escape, they must be opened, or at any rate a counter opening will be required: for *no abscess will ever heal unless the matter escapes from it as fast as it is secreted*. But it is not the lodgement of matter which under ordinary circumstances prevents an abscess or sinus in the groin from healing. It is the diseased glands at the bottom of it. If you want the sinus to heal, you must either destroy the diseased glands, or bring them into a healthy condition; sometimes it may be worth while to dissect out the glands, or to destroy them by powerful escharotics, but in the great number of cases, if you attend to the general health, they recover of themselves, and so soon, and no sooner, will the sinuses in the groin heal.

The same observation applies to sinuses that are connected with dead bone. A sinus of this kind does not heal, but becomes fistulous, because there is disease at the bottom of it. If the dead bone comes away it will close at once. It is needless to lay open the sinus, to inject stimulating liquors into it, or to do anything else until the dead bone is removed: and then nothing more is wanted.

COLLEGE OF SURGEONS.

To the Editor of the Medical Gazette.

SIR,

IN your number for January 20, I see a letter from Mr. Lee, in which he complains that he has not been honoured with a place in the first list of Fellows of the Royal College of Surgeons of England. Now, if Mr. Lee considers a little, he will find that there are others who have done something perhaps equal to his labours, and whose names are not to be found in the list. It is very well known that the Council had not the opportunity of including all the names they could desire in their first list, and there is every reason to believe that they did that which they considered to be fair and just:

the list bears internal evidence of plan and design, and no plan could be acted upon that would please every body. I would advise Mr. Lee, and all others who consider themselves aggrieved by the selection of Fellows, to wait patiently for the second list, in which the names of those members who have by their labours extended the bounds of medical science will doubtless appear; but let such members bear in mind that making a book and extending science are not the same thing. Many a great writer has contributed but very little to the stock of solid knowledge; the founders of science should at least be considered equal to those who are the mere teachers of science. Our first men are the discoverers of facts, and the founders of recognised principles; then the highly instructed teachers and authors; then the senior members of high character. If members are placed on the next list who have nothing on which to found a fair claim for distinction, and men of publicly acknowledged talent are excluded, then there will be cause for complaint; but such it can hardly be thought will be the case.—I am, sir,

Your obedient servant,

A TWENTY-EIGHT YEARS MEMBER
OF THE COLLEGE.

London, January 20, 1844.

QUACK ADVERTISEMENTS.

To the Editor of the Medical Gazette.

SIR,

THE countenance afforded to quacks and quackeries is a standing complaint among all classes of our profession. I would suggest, therefore, whether you and other journalists are not doing much to encourage such delinquents by allowing the insertion of their "puffs" in your advertising sheets. I am induced to make these remarks by the notice of a sale of an infallible cure for gout, in your journal of Jan. 19. The same thing has occurred in the *Lancet*—(vide an advertisement by a Dr. Serney, who has published some mystifications concerning "two electric fluids," in *Lancet*, Jan. 13th.) Surely, sir, it is inconsistent with the dignity of either yours, or Mr. Wakley's journal, to admit advertisements which are only worthy of the pages of the *Weekly Dispatch*. I remain, sir, in the hope of inducing you to notice this subject.

Your obedient servant,

F. H. RANKING, M.D.

Bury St. Edmunds.

[We have nothing to do with the advertising department—controlling only the *body* of the journal, not the wrapper.—*Ed. Gaz.*]

THE NORTH DUBLIN UNION HOUSE.

NEAR to the Stoney-batter lies a group of huge gloomy edifices—an hospital, a penitentiary, a madhouse, and a poor-house. I visited the latter of these, the North Dublin Union-house, an enormous establishment, which accommodates two thousand beggars. Like all the public institutions of the country, it seems to be well conducted, and is a vast orderly and cleanly place, wherein the prisoners are better clothed, better fed, and better housed than they can hope to be when at liberty. We were taken into all the wards in due order—the schools and nursery for the children; the dining-rooms, day-rooms, &c. of the men and women. Each division is so accommodated, as also with a large court or ground to walk and exercise in.

Among the men, there are very few able-bodied, the most of them, the keeper said, having gone out for the harvest time, or as soon as the potatoes come in. If they go out, they cannot return before the expiration of a month: the guardians have been obliged to establish this prohibition, lest the persons requiring relief should go in and out too frequently. The old men were assembled in considerable numbers in a long day-room that is comfortable and warm. Some of them were picking oakum by way of employment; but most of them were past work, all such inmates of the house as are able-bodied, being occupied upon the premises. Their hall was airy, and as clean as brush and water could make it: the men equally clean, and their gray jackets and Scotch caps stout and warm. Thence we were led, with a sort of satisfaction, by the guardian, to the kitchen—a large room, at the end of which might be seen certain coppers, emitting, it must be owned, a very faint inhospitable smell. It was Friday, and rice-milk is the food on that day, each man being served with a pint-canful, of which cans a great number stood smoking upon stretchers—the platters were laid each with its portion of salt, in the large clean dining-room hard by. "Look at that rice," said the keeper, taking up a bit, "try it, sir, it's delicious."—I'm sure I hope it is.

The old women's room was crowded with, I should think, at least four hundred old ladies—neat and nice, in white clothes and caps—sitting demurely on benches, doing nothing for the most part; but some employed, like the old men, in fiddling with the oakum. "There's tobacco here," says the guardian in a loud voice, "who's smoking tobacco?" "Fait, and I wish dere was some tabacky here," says one old lady, "and my service to you, Mr. Leary, and I hope one of the gentlemen has a snuff-

box, and a pinch for a poor old woman." But we had no boxes; and if any person who reads this visit goes to a poor-house or lunatic asylum, let him carry a box, if for that day only—a pinch is like Dives's drop of water to those poor limboed souls.—*Titmarsh's Irish Sketch-book.*

[The wretched diet of our Union Work-houses has long been a subject of complaint among English philanthropists; but such is the unutterable misery of the Irish poor, that no poor-law commissioner can outbid it; and even boiled rice may rank as a luxury at Dublin!—Ed.]

THE DATE-TREE.

THE extensive importance of the date-tree is, says Dr. Clarke, one of the most curious subjects to which a traveller can direct his attention. A considerable part of the inhabitants of Egypt, Arabia, and Persia, subsist almost entirely on its fruit. They make a conserve of it with sugar, and even grind the hard stones in their hand-mills for their camels. In Barbary they form handsome beads for paternosters of these stones. From the leaves they make couches, baskets, bags, mats, brushes, and fly-traps; the trunk is split and used in small buildings, also for fences to gardens, and the stalks of the leaves for making cages for their poultry. The threads of the web-like integument at the bases of the leaves are twisted into ropes, which are employed in rigging small vessels. The sap is obtained by cutting off the head of the palm and scooping out a hollow in the top of the stem, where, in ascending, it lodges itself. Three or four quarts of sap may be obtained daily from a single palm, for ten days or a fortnight, after which the quantity lessens, until at the end of six weeks or two months, the stem is exhausted, becomes dry, and is used for firewood. This liquor is sweetish when first collected, and may be drank as a mild beverage, but fermentation soon takes place, and a spirit is produced, which is distilled, and forms one of the kinds of aruk (arrack) or spirit of Eastern countries. Such being the importance and multiplied uses of the date-tree, it is not surprising that in an arid and barren country it should form so prominent a subject of allusion and description in the works of Arab authors, and that it should be said to have 300 names in their language. Many of these are however applied to different parts of the plant, as well as to those at different ages.—*Miss Burnett's Illustrations of Useful Plants.* January, 1841.

[We are glad to find that this agreeable work continues to prosper. It has now reached its fifty-first number.—Ed.]

OBSCURE CASE OF SUPPOSED INFANTICIDE.

BY MM. THIBAUD, THUILLIER, AND
MONTANCEIX.

A WOMAN asserted that she had delivered herself of a dead foetus on the 24th of September; that she placed it in brandy the same day, took it out on the 26th, and replaced it on the 27th; and that on the 29th she took it, for the last time, out of the brandy, and immediately put it into spirits of wine, where it remained till the 12th of October, when it was taken out of the vessel to be submitted to scientific examination. The question to be solved was, how long the foetus had been in the alcohol; and whether the spirits of wine would have been able, in the supposed time, to produce the observed effects? The *experts* endeavoured, in their experiments, to reproduce the precise circumstances in which the foetus submitted to their examination had been placed. They concluded from them, that the foetus was in the beginning of the seventh month of intra-uterine life, and that it was not the one of which the woman said that she had delivered herself on the 24th of September.—*Annales d'Hygiène*; and *Gazette Medicale*.

A DANISH MEDICAL JOURNAL.

WE take shame to ourselves for not having sooner noticed an excellent foreign journal, of which fifteen numbers are now lying before us. It is published at Christiania, in the Danish language, every two months, each number containing about 100 pages. It is entitled *Norsk Magazin for Lægevidenskaben, udgivet af Lægeforeningen i Christiania*. The names of the editors are Chr. Boeck, A. Conradi, Chr. Heiberg, J. Hjort, and F. Holst.

Should we be favoured with any more numbers, the editors would add to the obligation by sending a translation of a couple of articles into English, French, or German; as the Scandinavian languages are, unfortunately, but little studied in this country.

We cordially wish the *Norsk Magazin* the success which it so richly merits.

ON THE EMPLOYMENT OF COCHINEAL IN THE TREATMENT OF HOOPING- COUGH.

DR. CAJETAN WACHTEL, of Vienna, treated nine children, suffering from hooping-cough, with cochineal, as recommended by certain English physicians. The remedy was administered in all stages of the disease; and its efficacy was so instantaneous and constant, that, notwithstanding the paucity of cases, Dr. Wachtl feels authorized to regard cochineal as a specific in hooping-cough. The

following is his manner of exhibiting the remedy:—Take of cochineal, one scruple; sugar, one ounce.—Dissolve in six ounces of warm water. The dose is three tea-spoonfuls in the twenty-four hours.

The solution ought not to be kept longer than thirty-six or forty-eight hours, because after that time it assumes a brown hue, and a sour taste, which renders it unfit for use.—*Pharmaceutical Journal*.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS.

THE annual dinner of this Society is appointed to take place on the 20th of February (Shrove Tuesday). It is hoped that H. R. H. the Duke of Cambridge will take the chair.

APOTHECARIES' HALL.

ON
DIFFERENT FORMS OF GRANULAR
DISEASE OF THE KIDNEY.

By J. D. HEATON, M.D.
(*For the Medical Gazette.*)

THE following cases are, I think, of sufficient interest to be worthy of insertion in your journal; they are taken, with the accompanying remarks, from the Fellows' Prize Reports by myself, of cases which occurred in University College, London. Those which I shall first offer are some cases of different forms of granular disease of the kidney, of which several cases occurred together.

Joseph Wilson, admitted under Dr. Williams, June 7, 1841. 45 years of age, occupation, a house-painter; a married man, middle stature, sallow complexion, dark hair. His general health has been good; his habits quite temperate.

About a month ago, he caught a severe cold, which laid him up for some days. It was while recovering from this, and a day or two after returning to his work, that he first perceived his body to swell without any apparent cause, as he felt in pretty good health. He continued at his work a few days, but as the swelling increased, and he began to feel exceedingly weak and languid, though without any pain, he was obliged to discontinue his occupation. He had no palpitation at the heart, nor pain in the chest, nor in the loins, or any other part. His water was more scanty than usual, and of a high colour, but clear; his bowels were constipated till he took some medicines by medical advice, which purged him profusely. After this he was salivated, but still continued getting worse, and more dropsical. While under the effects of mercury, he caught cold, and had a severe cough with much expectoration. Two days before ad-

mission, he first experienced a sharp lancinating pain in the right chest, shooting between the shoulder and the sternum.

At the time of his admission, the symptoms were as follows:—The feet, legs, and thighs, were highly oedematous, pitting deeply on pressure; the penis and scrotum were distended with serum; the abdomen was anasarcaous, with distinct fluctuation, but without tenderness; the upper extremities were also oedematous, but the face not so. There was an ulcer on the right shin, which formed spontaneously three months ago, and still continued open. He complained of much dyspnoea; the respiration was short and hurried; he had some cough, but this was less troublesome than it had been, and there was little expectoration; he could breathe most easily whilst lying on the right side. He still suffered from the pain in the right side, increased by a deep inspiration. The tongue was covered with a dark brown fur, moist, but adhesive; the gums presented the effects of mercury, and the breath had a strong mercurial foetor. The bowels were much purged from the effects of medicine taken previously, the stools having a natural faeculent colour. The urine was very scanty, rather turbid, of a high colour, and gave a very copious flocculent precipitate with the usual tests for albumen; its sp. gr. 1032; it slightly reddened litmus paper. Much headache; pulse frequent, small, and feeble; surface dry and unperspiring. The respiratory movements of the chest were more extensive on the left than on the right side; the latter being fixed in a distended state, and the subclavicular spaces being unusually resonant, but completely dull in the inferior and lateral parts: on the left side the stroke sound had the usual resonance. On each side, under the clavicle, the respiration is tubular, especially under the right clavicle, where the respiratory murmur is almost entirely absent; at the inferior angle of the right clavicle oëgophony is distinguishable. The sounds of the heart are natural, with

the exception of a slight roughness heard at the base with the first sound.

Lateri dextro admoveatur emplastr. Canth.

℞ Pilulæ Hydrargyri, gr. iij. ; Ext. Ilyoseyani, gr. ij. ; Pulv. Scillæ, gr. j. M. ft. pil. ter die sumenda. Bibat. Potum. Potas. Bitart. ad lib.

8th.—Not much change in the symptoms ; stools liquid ; urine very scanty, dark-coloured, and turbid ; highly albuminous. Tongue rather dry. Pain in the chest relieved by the blister.

Rep. Pilula c. Pulv. Digitalis, gr. ss. vice Pil. Hydrarg.

℞ Tinct. Cantharidis, ℥x. ; Liquoris Potassæ, ℥xx. ; Sp. Ætheris. Nit. ʒj. ; Mist. Camph. ʒj. ; M. ft. haust. ter die sumendus.

10th.—No improvement in the symptoms. The countenance pale, and expression very anxious. The pain in the chest more severe ; respiration short, painful, and principally abdominal. Still much diarrhœa. Tongue brown and adhesive ; pulse 100, with some sharpness, but small and feeble. The urine presenting the same appearances as before ; very scanty, not amounting to more than two or three ounces in the 24 hours. Body chill, but slightly perspiring.

Fiat Venæsectio, ad xij.

Foveatur abdomen c. Decoct. Papav. Calido.

11th.—The blood drawn yesterday presents a moderately firm coagulum, but is neither cupped nor buffed, which, however, may depend on the great slowness with which it flowed when drawn ; the serum very small in quantity. The patient seems relieved by the bleeding ; the countenance is less anxious ; the pain and tenderness of the body are diminished, and the abdomen seems less tense. No increase in the amount of urine.

Aug. Tr. Canth. ad ℥xv. in sing. dos.

Lateri dextro admoveantur Hirudines, xij.

12th.—Considerably worse ; countenance pale and anxious ; tongue brown, and quite dry ; sordes collecting on the teeth ; pulse 100, very small and feeble. The cough is more troublesome, and accompanied with a rusty viscid expectoration, having some streaks of blood. The physical signs afforded by the chest are similar to those previously described, but those indicative of effusion in the right chest are still more marked ; the respiration, and even the stroke sound in the upper part, having quite a tubular character as the patient lies on his back. Diarrhœa still profuse ; no increase in the quantity of urine.

℞ Decoct. Scoparii Co. ʒiv. ; Potass. Nitratis, gr. x. ; Sp. Æther. Nit. ʒj. Sodæ Sesquicarb. gr. x. M. ft. haust. ter die sumendus.

14th.—Some improvement in the patient's general appearance, with a slight increase in the amount of urine since the use of the last medicine, but it is still highly albuminous. The diarrhœa still continues. The pulse has fallen to 90, and has rather more strength ; the tongue brown, but quite moist. The cough is very troublesome, and he complains of much dyspnoea ; but there are no head symptoms. Very slight perspiration.

℞ Pulveris Antimonialis, gr. iij. ; Pulv. Ipecac. Co. gr. vj. ; M. ft. pulv. omni nocte sumendus.

16th.—The improvement mentioned in last report still seems to continue in the general symptoms, but there is no increase in secretion of urine, which does not amount to above three or four ounces in the twenty-four hours ; it is very dark in colour, turbid, and has a strongly urinous mixed with an ammoniacal odour ; it is highly albuminous, and has a sp. gr. of 1021. He is still much purged ; the tongue furred, but moist ; skin unperspirable.

Repetatur Haust. c. Tr. Opii. ℥v. vice Potas. Nitrat.

17th.—The symptoms continue much the same ; the diarrhœa is rather diminished by the opium. The signs of effusion in the right chest are still well marked. The œgophony has ceased ; there is a slight friction sound in the right mammary region. Cough very troublesome. The whole surface is œdematous ; there is much œdema about the neck, and probably to this may be ascribed a choking sensation, as of pressure on the throat, of which he complains.

18th.—Seems considerably worse, the physical depression being much increased since last report, though without distinctly typhoid symptoms.

19th.—Extremely depressed ; answers are given in a low whisper ; feels confused in the head, and very drowsy, but is unable to get any sleep. Seems much choked with mucus in the air passages, which he has not strength to expectorate. Pulse 100, very small and feeble ; tongue brown and quite dry. What urine is passed dribbles away involuntarily ; the last which was collected has still a very copious precipitate on the addition of nitric acid, but ebullition causes no precipitate, without nitric acid, which shows some singular change in the property of the albumen contained, which has not been the case on previous examinations. The diarrhœa still continues, and the urine like the stools are discharged unconsciously. The body seems still more distended by the dropsical effusion ; the wounds in the arm from venesection remain unhealed, and now form open ulcers discharging a thin watery pus.

Adde Haustui Potas. Acet. ʒss.

21st.—Evidently near his end. The

countenance pale, face shrunk, and having an anxious expression. Respiration moaning, and very short and hurried; the voice reduced to a feeble whisper. He gives intelligible answers, but appears heavy and confused, and gets no sleep. Tongue dry and brown; pulse 120, scarcely perceptible. The body is quite dry, but there is a copious perspiration from the head. The excretions are passed involuntarily.

He died about ten o'clock this evening.

Inspectio cadaveris, post-mortem horas xv.

External appearance.—The body highly œdematous in all parts, except the face. The ulcers in the leg, and on the arm from venesection, covered with a thin watery discharge. The abdomen and right chest distended with fluid.

When the *thorax* was opened, some pints of clear serum escaped principally from the right side. Flakes of greenish semi-purulent lymph covered the lower part of the right pleural membrane, which presented much inflammatory injection when the lymph was removed, and there was a similar appearance, though in a smaller degree, on the left side.

The *right lung* was somewhat condensed and injected throughout, and less crepitant than usual. Near the apex were groups of miliary tubercles of considerable firmness; and numerous miliary granulations were scattered throughout the whole lung. The lower lobe of this lung was much condensed, and was the seat of inflammation of a lobular or distinctly circumscribed character. A section of this part showed the great mass of the lung of a dark red colour, but interspersed in this were numerous patches of irregular shape and size of a more fluid red; these were quite solid, sinking in water; but when torn they presented a uniform surface without any granular appearance, presenting that state to which the name of carnification has been applied.

The *left lung* was attached to the walls of the chest posteriorly by firm old adhesions. It was much congested throughout, but without any of the tubular inflammation seen in the other lung. The substance of the lung was soft and easily torn, and much frothy serum oozed from the cut surfaces when compressed. Near the apex was a portion completely dense and consolidated, the tissue of the lung being puckered around. Miliary tubercles were scattered through the upper lobe. The bronchial lining membrane in both lungs was injected, and in some parts considerably hypertrophied.

The *pericardium* contained much fluid; the heart was free from disease.

The *right kidney* was slightly enlarged; soft and flabby and easily lacerable, the capsule easily removed, but bringing with it

small portions of the glandular substance, which had a pale, brownish-yellow colour, interspersed with lighter albuminous patches; some parts of the surface almost smooth, others finely granulated; the albuminous patches extended through the depth of the cortical structure, but did not much invade the tubular part. There was little difference of colour between the tubular and cortical structures, being pale and faded throughout, marked, however, in the cortical part, by numerous stellated spots of vascularity.

The *left kidney* was larger than the right, and more soft and easily lacerable, as well as more granular. The granulated appearance, in the right kidney confined to the cortical, here dipped into the tubular structure between the separate cones: some of the tubes appeared distended with the morbid deposit. The stellated vascularity was more marked in this than the right kidney.

The right kidney weighed $5\frac{1}{2}$ ounces; the left 7 ounces.

The liver was rather small; yellower than usual, and of a paler colour; the central red points of the individual lobules, formed by the intra-lobular hepatic veins, appeared smaller than usual, and surrounded by a larger, pale cortical portion. The weight was 3lbs. 5 ounces.

The peritoneal cavity contained a considerable amount of serum. The intestines presented much vascularity throughout.

The symptoms here are almost all referrible to the granular disease of the kidneys, of which this case is a good illustration; it may be considered as an instance of the acute disease, for not more than five weeks intervened between the time when the dropsy first attracted his attention, and his death. Exposure to cold seems to have been the exciting cause of his disorder, and this may have determined the thoracic complication, though the disease itself strongly predisposes to inflammatory affections of various parts, and particularly of serous membranes. Previously to his admission into the hospital he seems to have been treated for the dropsy simply, without any reference to the cause of this, viz. the disease in kidneys, and probably the mercurial treatment adopted was injurious rather than beneficial. The dropsy was very general, though it did not, as it frequently does in this complaint, extend to the face. The effusion in the chest, though it might be increased by the general tendency to effusion throughout the body, yet was evidently of an inflammatory nature, being accompanied with many of the general symptoms of pleurisy, and being confined principally to one side of the chest, on which side, also, the crepitation which was heard at one time shewed the presence of pneumonia. The low character of

the inflammation, as well as its obstinacy, must be regarded as depending on the impure state of the blood, impregnated with the urea which the kidneys, in their diseased state, were unable to separate.

The diarrhœa which existed at the time of the patient's admission, having been excited, in the first instance, by the administration of powerful purgative medicines, continued till his death. This is a frequent, and, in unfavourable cases, often a troublesome symptom in this disease: though unfavourable when obstinate, yet it is perhaps not in itself injurious: where remedies prove beneficial, the administration of purgatives is one of the most useful means, and when diarrhœa is set up, or continued spontaneously, it may probably be fairly regarded as an effort of nature to remove part of the fluid from the blood, and perhaps also some of the injurious principles, especially the urea, which should be eliminated by the kidneys. Hence this symptom may be regarded as unfavourable, rather as shewing the continued inefficiency of the kidneys, and from its obstinate and troublesome character, than injurious in itself. The remedies administered to relieve this symptom were certainly not powerful, as it was feared that the sudden stoppage of the diarrhœa might aggravate the other symptoms.

The complete absence of local symptoms in the kidneys is remarkable, and shows that these are by no means essential even to a severe and acute form of this serious disease of those organs; but the characters of the urine gave decisive evidence of the true nature of the affection. Not merely the serum of the blood was allowed to pass through the diseased structure of the kidneys with the urine, but probably also some of its colouring matter, giving to the urine its deep colour. The sp. gr. was rather higher than that of healthy urine at the time of his admission, but when we consider its very small quantity, and also the large amount of albumen which it contained, we shall see that the urea and other principles contained in healthy urine must have been retained in the blood, and indeed before death the sp. gr. fell below the healthy standard. In these cases urea may be easily found in the serum of the blood, and proves a dangerous poison when so retained; whether lithic acid, separately or in combination, be also to be found in the blood in this disease, and what its effects are on the system, have not been so much investigated. The alteration in the albuminous principle contained in the urine at one period, rendering it incapable of coagulation by heat, though still acted on by nitric acid, was remarkable, and worthy of consideration: the observation was too carefully made to be liable to mistake.

Death, in these cases, seems dependent on the poisonous effect of those principles retained in the blood; the poison appears to act principally on the brain; headache and stupefaction, gradually passing into coma, usually precede death for some days. In this case, however, there was a remarkable absence of these head symptoms, and the symptoms which preceded the fatal event more resembled those of the last stage of typhus.

The impure state of the blood was further indicated by the inability of the system to establish the ordinary reparatory process, shown by the unhealthy appearance of the wounds in the arm produced by venesection.

Little remark is required with regard to the treatment adopted.

The serious general symptoms, and the very small quantity of urine that was secreted, and its highly albuminous state, led to an unfavourable prognosis from the time of his admission; and it seemed probable that the opportunity for active local depletion was already passed; various remedies were tried to increase the action of the kidneys, but without effect. The treatment for the removal of the inflammation in the chest was likewise not very successful; the general disorder forbade the use of very active measures, and, at the same time, increased the tendency to low inflammation.

The *post-mortem* appearances were such as would naturally be expected from a consideration of the symptoms during life. The marks of inflammation in the right chest, both pleuritic and pneumonic, very well corresponded with the symptoms and signs observed previously. In the left chest the stroke sound had been quite resonant when examined during life; the stethoscope, also, had not disclosed the signs of pulmonary congestion; still this state was found to exist in a considerable degree when the body was opened. It is probable, therefore, that this supervened only shortly before death, being a kind of engorgement which very frequently supervenes in the last stage of fatal diseases when the respiration is carried on very imperfectly for some time before death; being the state to which Laennec has given the name of *pneumonia ugonizantium*.

The pale colour of the liver, and its small size, probably depended on a morbid deposit having a tendency to contract, similar to that of cirrhosis: some reference may be made again to this subject in speaking of another case.

The appearances in the kidneys were such as usually present themselves in acute fatal cases of granular disease of the kidney. Various opinions have been entertained as to the nature of this disease: some remarks will be made on this point after giving the other reports of similar cases.

Leeds, Jan. 1844.

CLINICAL REPORT

OF THE

BRITISH DISPENSARY IN SYRIA.

To the Editor of the Medical Gazette.

SIR,

IN the MEDICAL GAZETTE for the 17th of March, 1843, you were kind enough to publish the "Clinical Report of the British Dispensary in Syria"—the first ever transmitted from the Levant; and as every thing connected with the east is viewed with increasing interest, I doubt not a further account of our proceedings will be acceptable to your readers. Not to trouble you, however, with too lengthy an address, I must refer those who are unacquainted with the climate and general condition of Palestine to my former remarks, and to the published "Transactions and Reports of the Syrian Medical Aid Association."

I am sure it will be gratifying to you to learn that the efforts of our agent here have succeeded; and that by his assiduity, good conduct, and professional skill, he has secured the entire confidence of the people. During the first six months of his residence, he relieved, under every disadvantage, 623 males, and 674 females, which, added to the returns of the two succeeding quarters, as included in the following table, make a total of 2298 cases for the entire year, *i. e.* up to last September; and he has performed several important surgical operations to the perfect satisfaction of all parties.

Report of the British Dispensary at Beyrout, Syria, from September 1842 to September 1843:—

	Cases.
Ophthalmia	993
Purulent ophthalmia	16
Pterigium	12
Eutropium and ectropium	35
Cataract	22
Amaurosis	5
Intermittent fever	313
Continued fever	144
Puerperal fever	10
Rheumatism	429
Pneumonia and bronchitis	284
Phthisis	5
Inflamed tonsils	9
Dyspepsia	14
Diseased liver	46
Dysentery	62
Diarrhoea	35
Dropsy	3
Paralysis	18
Spinal diseases	4
Urinary diseases	63
Hysteria	4
Catamenial derangements	54

Eruptions	190
Worms	112
Cancer	8
Hernia	19
Hydrocele	3
Syphilitic complaints	16
Abscess	37
Ulcers	282
Tinea capitis	23
Hare-lip	5
Club-foot deformities	4
Deafness	47

4181

Cases not noticed above 117

Total during the Twelve Months 4298

Remarks upon the above report.

Ophthalmia.—"The universal prevalence of eye-diseases in these countries," observes Dr. Kerns, "will prepare the Committee for the large number of cases under this head, in which I have included every stage of the disease, from simple conjunctivitis to ulceration or opacity of the cornea, any subdivisions appearing useless. The disease, if neglected, or improperly treated, rapidly runs its destructive course; and the treatment adopted by the natives being mere quackery, the lamentable results are to be seen everywhere. It is difficult to assign the chief cause of ophthalmia in these countries, as it is to be found among all classes of every age, and under the most opposite circumstances. Exposure by sleeping in the open air, poverty, and want of cleanliness, have each, in turn, been named as the cause; but many cases have come under my notice to which none of these causes could apply. I am inclined to think that exposure to the unobscured light of the sun, arising from the peculiar head-dress, is amongst the most fruitful causes of this disease*.

Purulent ophthalmia is not a very frequent, but, as elsewhere, a very formidable disease; but if taken in time, it yields to the nitrate of silver and ordinary treatment.

* See my remarks on this subject in my last communication, (MED. GAZ. for March 17th, 1843.) Chronic disease of the eyes in Syria and Egypt is comparatively rare; for inflammation, if neglected (as it too frequently is), runs its course so rapidly that patients sometimes lose their sight in three days. The Mohammedans, being fatalists, trust everything to Providence, and often do nothing to help themselves. If they interfere at all, their plan is to take castor-oil, or some milk which has been allowed to stand on the pulp of the "bitter apple." Sometimes they apply the actual cautery, or scarify the back of the neck by means of a razor and a buffalo's horn—a very primitive but effectual mode of cupping; and they have recourse to the bath. But their treatment, as in every other case, is generally counteracted by inattention to diet, or by the most reckless exposure to the sun's rays. Young men very commonly put out their right eye that they may avoid the Conscription.—W. HOLY YATES, M.D.

Entropium is frequently met with, and I have operated with success in several instances.

Cataract.—Of 22 cases I operated on about 10, with various degrees of success. Some succeeded to the utmost: two were lost by subsequent inflammation, the patients having returned home; and as they lived at considerable distances, were of course beyond my reach. One completely successful case was a man nearly 73 years of age. He resided nine hours' distant from me, on Mount Lebanon. He subsequently came to see me at intervals; and on two occasions led other blind men to my dwelling, that they might obtain similar relief*.

Intermittent fever.—For this disease it is difficult to assign an evident cause. Marsh miasmata is out of the question where the land is parched with drought one half of the year; and at no period, in this district, are marshes or stagnant pools to be found of any extent: however, if we omit the association of marsh, which is but a casual circumstance, the theory of decomposed animal and vegetable matter will remain as probable as any other, and as applicable. These effluvia are often more offensive from the absence of water. The disease is here found among persons of all classes and all ages, and in many cases it recurs several times when the patient is supposed to be quite well. In such, change of air, either from the plains to the mountains, or the reverse, is attended with the most beneficial result. In cases of long standing, quinine appears to lose its effect. A gentleman told me, some time since, that he had finished an ounce bottle of sulphate of quinine, and yet ague still hung upon him, appearing at regular intervals†.

* In Mohammedan countries, disease is believed to have been sent by "Allah" as a punishment for sin; therefore it is accounted presumptuous to attempt to eradicate it; but if a "Hakim" passes by, the afflicted kiss the hem of his garment with superstitious veneration, and beseech him to "lay his hands on them, and heal them;" for every one who has the *gift of healing* is regarded by them as a man "sent from God," and they often call him "the man of God." They believe that he has the power to minister to all their necessities, and that he must be a good man to be endued with such power. If he refuse to help them (because it may be the case is hopeless) they think that "Allah" forbids him: but, on the other hand, if happily he cures them, they thank not him but "Allah." "Thanks," they say, "are due only to the Most High; all men are equal in the eyes of God, but it is a duty and a privilege to help our neighbour." They show their gratitude to man by acts; they thank God in prayer, and call down blessings on their benefactor! But they have no notion that the art of healing the sick may be acquired or taught.—W. HOLT YATES, M.D.

† In obstinate cases of ague, I have found a combination of five minims of the Eppor arsenicalis with two grains of sulphate of quinine, taken every four or six hours during the interval, cut short the paroxysm, when quinine or the liq.

Continued fever is generally of the common inflammatory form. I have met with very few cases which assumed a typhoid character. In persons of an ordinary full habit, fever in this country sometimes runs on rapidly to a fatal termination. The practice of the natives betrays lamentable ignorance, often consisting of the use of rose water, or some other useless article; but fortunately they are fond of bleeding, which, though sometimes injudiciously had recourse to, in many cases proves the sole means of saving life.

Rheumatism arises, in a great measure, from the habit of sleeping on the ground, upon only a mat or rug; and of course any other exposure to night or damp.

Pneumonia and bronchitis may also be justly ascribed to exposure, by sleeping in the open air, and to imprudence when heated to excess by exertion under a hot sun.

Pulmonary consumption is a rare disease in Syria. For patients thus afflicted, or having what is usually understood by "delicate lungs," if I may form an opinion after a single year's residence in this country, I think the winter climate cannot be surpassed by any other for salubrity.

Dyspepsia.—This complaint is very prevalent here, in some form or other, and appears to arise from the very large proportion of vegetables cooked with oil, which constitute the food of the natives, and the habit of eating unripe fruits.*

Diseased liver is by no means so frequent as might be expected from the prevalence of ague. But the people in general are sober: ardent spirits are little used.

arsenicalis alone has failed. The chief causes of fever are unquestionably, I think, sleeping in the open air, exposed to the heavy dews of the night; and the effluvia arising from vegetable matter which has been washed down from the neighbouring heights by the torrents in the rainy season, and left to decompose during the intense heat of summer. Dr. Kerns forgets that although there may be no "stagnant pools" on the shelving grounds between the sea and the mountains, there is abundance of moisture; for in these countries, the dew falls so heavily after sun-set, and so fast, that unless a man be duly prepared for it, it would wet him through in half an hour. Accordingly, we find that fever is most prevalent during the summers, and the resident merchants retire to the villages of Lebanon to avoid them. The effluvia generated by the putrid matter is always rendered most active when there is a combination of heat with a moderate quantity of moisture.—WILLIAM HOLT YATES, M.D.

* Add to this almonds and cinnamon, which are mixed up abundantly in almost every dish; the practice of treating their friends with sweetmeats, and the abuse of coffee and tobacco. Moreover, the females become corpulent, dyspeptic, and sallow, for want of exercise. I was once called to the Harem of one of the Druse Emirs of Lebanon. I found the "Princess Royal" rolling about on the divan in great pain, in consequence of having partaken too freely of "raw liver," and other similar dainties. Her attendants were fanning her, and bathing the soles of her feet with rose water!—WILLIAM HOLT YATES, M.D.

Dysentery is not more frequent than might be expected from the number of dyspeptic patients.

Dropsy, as far as I have yet seen, is decidedly a rare disease in this country.

Paralysis.—Of the cases enumerated, some were affected in the hand and foot; some the two feet; some the two hands; and others the muscles of the face. I have tried electricity, and electro-magnetic influence in some cases, with decided advantage; but not always.

Urinary affections.—These depended chiefly on irritation of the bladder. Chronic disease of its lining membrane is rather frequent; and, I think, arises from the excessive use of unripe fruit.

Hernia.—I have not yet met with a single case of strangulated hernia; but by means of the trusses which the Committee kindly sent me, I have been enabled to afford relief in several very distressing cases.

Ulcers, from whatever cause, are prone to assume a chronic character, and become exceedingly difficult to heal. I seldom find any benefit from oily applications: the remedies which I generally employ are astringents. There is a peculiar ulcer known here as the "Aleppo button," from its great prevalence in Aleppo.* It occurs but once, and is, for the most part, confined to one ulcer, beginning as a common pustule on the cheek, and extending to the size of a shilling or a half-crown. It runs its course in about twelve months; and, from all I can learn from the most intelligent residents in this country, it appears to resist every kind of treatment, *until the usual time*; after which it dries up, very frequently leaving a deep scar on the face. I have not yet had sufficient opportunity of investigating its nature, or of ascertaining the most suitable treatment, as few cases have come under my own observation, and the patients only paid me a few visits. In such cases the want of an hospital is very manifest.

Hare Lip and *Club Foot* deformities are not common. I have operated successfully on those which came under my care, and to the no small astonishment of both patients and friends!

Syphilis is not prevalent in this country. The cases which came under my notice ever generally of a mild character. How far the observation may be justified I know not, but this whole class of diseases is designated by the natives "Habbeh Frangee," the "Frank disease," or ("Button.")

Cancer.—I have only had one case which admitted of an operation, and this of a trivial nature. The other cases had been

long subjected to the irritating "nostrums" of the country.

The past twelve months have not been marked by any unusual sickness, and I believe we had no visitation of plague, though two cases were reported; but from their history and result, there is much reason to doubt its correctness.*

I regret that it is not in my power to make my report more satisfactory, by adding the result and detail of cases; but this I find quite impracticable, owing chiefly to the inconvenient distances which a great portion of the people come, and the unfavourable circumstances under which they are seen when they do come. I will attend to the suggestions of the committee, as far as circumstances permit; but in the present state of the country, I do not think a *post-mortem examination* at all practicable. Indeed, unless some such powerful influence as that of Mehemet Ali be enlisted in its favour, I think the day is yet far distant.

I forbear to make any comment on the above, beyond the few short notes which I have introduced *en passant*, especially as I have enlarged upon all these subjects in my recent work on Egypt.*

Dr. Kerns has not yet been in Syria a year and a half; nevertheless, he has collected some very valuable statistics; and, indeed, accomplished so much, that, as far as he is concerned, the undertaking is clearly no longer an experiment: its practicability is proved beyond a doubt. The records of the charity, supported as they are by the testimony of recent travellers, and of the resident merchants (who have been eye-witnesses of Dr. Kerns' labours) afford a convincing proof of the utility of the Institution; more particularly as in that widely extended territory (including a population of two millions) there is scarcely any resource besides that which the Association has provided. The Dispensary House at Beyrout is beset at all hours by persons of every denomination who are anxious to obtain advice for themselves or relatives. Many have to traverse the rocky regions of

* It is very commonly reported that the plague is raging in a particular district, when fever or any other epidemic prevails, or is unusually fatal, because (as I have already stated) the natives regard every severe malady as a plague sent as a judgment from above. The Copts and Arabs believe that every person who dies in Egypt, no matter how young or old, falls a victim to the true plague, and assert that this has been the case ever since the Angel of the Lord "smote the first-born." Hence they call the disease "Taun," which signifies "the wound of a lance," and they think that the blow with a lance is inflicted by the destroying Angel.

The more experienced European residents understand by "a plague" a *great deal of sickness*.
WM. HOLY YATES, M.D.

* See Russell's "History of Aleppo," and his "Treatise on the Plague of Aleppo;" also "Maundrell's Journey from Aleppo to Jerusalem."

* "The Modern History and Condition of Egypt: its Climate, Diseases, and Capabilities, &c. 2 vols. 8vo." Smith, Elder, and Co. 1843

Lebanon, a distance of thirty and forty miles, whilst others come even from Damascus, because in that great city there is not a single medical man who has the slightest claim to their confidence; those who profess the "healing art" being either "charm venders," "magicians," or "adventurers!" The following extract of a communication from Dr. Kerns, dated Nov. 10, 1843, affords a striking illustration of this.

"In compliance with the wish of the Committee that I should make a visit of inquiry to Damascus, I have done so, and just returned. I stayed a fortnight there, and saw several patients. There are no European physicians or surgeons, except Italians and Poles, who, in this country, are generally *mere quacks*. I have no doubt but a physician would be well received there, but his expenses would be little less than at Beyrout.

"During my stay I was called to attend the lady of a Scotch missionary in the capacity of accoucheur. This being her first confinement, she was very anxious, and re-

garded my opportune visit as a providential circumstance. I had the pleasure of leaving both mother and child well.

"The road from Beyrout to Damascus is very bad; it lies across the Lebanon and Anti-Lebanon mountains, and the journey took me two days and a half. Whilst travelling, I witnessed a curious specimen of Syrian surgical practice. A man fell from a walnut-tree, a height of 30 feet: his arm was broken, and his body severely bruised. On taking him up, the people instantly killed a sheep, and stripping off the patient's clothes, wrapped him up in the warm sheep-skin (the fleshy side inwards), *broken bones and all*, like a mummy! I saw him twelve hours after the accident, and he was then *steaming* in his new dress. Hearing who I was, they very gladly availed themselves of my services, and I left them quite satisfied with a more enlightened plan of treatment. I am happy to say my dispensary goes on prosperously. The weather is very pleasant now, being cool," &c.

THERMOMETRICAL TABLES.—SYRIA.

	AVERAGE.			AT NOON.		
	Morning.	Noon.	Evening.	Highest.	Lowest.	
1842						
Sept.	80	87	83	95	80	{ A heavy fall of rain, with thunder, for several hours. Thunder showers very rarely occur so soon.
Oct.	79	84	81	91	76	{ Some slight sprinkling of rain from a passing thunder-cloud on the 10th and 22d.
Nov.	65	71	64	77	64	{ Eleven days were more or less rainy. Snow on the heights of Lebanon on the 24th.
Dec.	59	64	61	76	57	{ Ten days rainy. On the 24th, snow fell as low as the village of B'Hamdoon.
1843						
Jan.	54	63	58	70	54	{ Twelve days rainy. Hail, slightly mingled with rain, on the 9th and the 21st.
Feb.	57	67	58	75	59	Nine days rainy, besides occasional sprinklings.
March	62	68	61	76	57	Seven days rainy. A remarkable comet appeared on the 4th.
April	64	68	65	77	58	Rain fell on nine days this month.
May	67	73	69	80	60	Rain fell on four days.
June	72	78	70	84	72	Five minutes light rain this month.
July	79	88	80	95	80	No rain.
Aug.	81	89	83	96	84	No rain.

At B'Hamdoon, a village on Mount Lebanon, about 4500 feet above the level of the sea, the thermometer stood as follows:—

July	72	75	73	77	68	No rain.
Aug.	69	71	70	84*	66	{ * During a Sirocco.
Sept.	69	73	72	83*	62	
Oct.	62	70	69	82*	53	

In all the above instances the thermometer stood in the shade. Rain fell in Beyrout on 62 days in the year. On 12 days of the 62, however, there was only a slight sprinkling, but on the remaining 50 days there was heavy rain.

(Signed)

THOMAS KERNS, M.D.

"Thus, then, it is manifest, that the prejudices of the natives, from which so much was at first apprehended, are entirely overcome; and the Turks, so far from offering any opposition to our agent, are anxious to place themselves under his care: they bring their dearest relatives, and even solicit his aid in behalf of the ladies of their harems. Dr. Kerns frequently has occasion to allude to this; and in one of his last letters, he writes—"It will be pleasing to the Committee to learn, that *universally* a feeling of gratitude prevails among those who have been the objects of our care; and the deference paid to British medical science is highly gratifying to myself; it is a matter which calls forth my earnest acknowledgments to a kind providence, that I have been thus far enabled to carry out the benevolent intentions of the Society, without being materially thwarted by native prejudice or arrogance. Notwithstanding the seclusion which custom has imposed upon the females of these countries, they constitute half the number of applicants at the dispensary, which, in itself, shews how much the people value the benefits conferred upon them. My patients consist of Jews, Moslems, Druses, and those of every christian sect in Syria; and not less varied in their class or rank in society,—from the Albanian soldier and Arab camel-driver, to the pascha on his divan. I frequently have the officials of the Turkish government, and also some of the most respectable emirs and scheikhs of Mount Lebanon, with the members of their families: and though such cases may not strictly come within the province of a charitable institution, still, as they gratefully accept gratuitous aid, I never hesitate to grant it (trusting to their generosity to contribute to the funds, or at least to facilitate, by their influence, the objects which we have in view), being persuaded that in so doing, I shall meet the wishes of the Committee, and impress the Syrians with the true and disinterested nature of that christian benevolence which animates their friends in England."

I am afraid, sir, I have already trespassed too much upon your liberality; I will only, therefore, add, in conclusion, that we have not given up the idea of opening a hospital at Beyrout, or of sending agents to the other principal towns, as contemplated in 1842, when the institution was first established. There still remains a great deal to be done, but I am sorry say that the state of our finances does not keep pace with our desire to do good; and the utmost we can hope to accomplish at present for these afflicted and enduring people is a continuance of those benefits, which, through the exertions of Dr. Kerns, we have hitherto been permitted to confer.

Once more thanking you on the part of the association,

I have the honour to remain, sir,

Your obedient servant,

W. HOLT YATES, M.D. &c.

53, Woburn Place, Russell Square,
January 27, 1843.

THE OPINION

OF

DR. WILLIAM HUNTER

ON

THE REMOVAL OF OVARIAN TUMORS.

To the Editor of the Medical Gazette.

SIR,

THE following quotation, containing the opinions of Dr. William Hunter respecting the removal of ovarian tumors, appears to me to bear upon the discussions of the present day, on the same subject. I am not aware that the passage has been quoted by any of the recent writers on the subject; and as Dr. Hunter was, to use the words of the late Dr. Gooch, "a man of great talents and knowledge, singularly adapted for natural investigations, and remarkable for clearness of intellect and correctness of judgment," some of your readers may be glad to know his opinions on the subject.

"The encysted dropsy of the ovarium is a case which has a less chance still of being carried off by scarifications in the legs, when complicated with an anasæra. Purging, &c. does still less towards evacuating the waters in this case, whether fluid or gelatinous, than in the common ascites. I have had occasion to see a great number of encysted dropsies, many of them treated by physicians of the first rank, and yet have never seen one cured; nor have I ever known one case of that kind, where the cyst has been sensibly diminished in bulk by any other means than by the trocar. If I may form a judgment by what I have seen, both in the living and in the dead body, I should believe that the dropsy of the ovarium is an incurable disease; and that a patient will have the best chance of living longest under it, who does the least to get rid of it. The trocar is almost the only palliative. It has been proposed, indeed, by modern surgeons, deservedly of the first reputation, to attempt a radical cure by incision

and suppuration, and by the excision of the cyst. I am of opinion that excision can hardly be attempted; and that incision and suppuration will be found by experience to be an operation that cannot be recommended, but under very particular circumstances." That the reader may see what this opinion is founded upon, I will give a concise account of the nature of the dropsy of the ovarium, as it has appeared to me in a number of cases, both in the living and dead body. It is generally of considerable size, as big as a pint bottle for example, before it is discovered; for the patient generally has neither bad health nor pain to put her upon an early inquiry, and while it is small, it is perceptible only in particular situations. At first it is commonly situated towards one side of the lower part of the belly, and is moveable under the hand: then it becomes gradually more fixed, more extended both forwards and upwards in the belly, and more painful and oppressive to the patient, &c. When the cyst is single, and extended over the whole abdomen, it cannot be distinguished by the feel from a common ascites; till then it can hardly be said to resemble the ascites. When there are a number of cysts, we are generally sensible of the inequalities and the swelling, from first to last. In the dead body, upon examination we find they take their origin from the ovarium, or adjacent parts at the ligamentum uteri latum. But when small, and when so large as to contain several quarts, they are sometimes detached or loose all around, except just at their origin; but more commonly they are found to have contracted partial and irregular adhesions to the neighbouring parts, seldom if ever to the floating loose turns of the bowels. When they are come near to their utmost extension, they sometimes adhere uniformly and universally to the parietes of the abdomen; but more generally, even in this case, the adhesion is partial and irregular. When there is only one coat, it generally, if not always, contains a thin water; where there are many, some of them more commonly contain a rosy fluid, in consistence like gall or thin honey; and others a gelatinous substance. The thin water is usually clear, the rosy fluid of a dark

brown colour, and the jelly sometimes less clear and transparent than the white of an egg: sometimes it is mixed with opaque white parts; sometimes it is of an amber colour; and at other times dark and brown. All this variety has been found in the same person. I can hardly say that I have ever found any part of a dropsical ovarium in a truly scirrhus state. What at first view might seem such, proved, upon cutting, to be a compact group of small bags; or a spongy substance filled with jelly. Generally, before the patient dies of such a dropsy, some degree both of leucophlegmasia and of ascites is brought on; so that when such bodies are opened some water is found loose in the cavity of the belly; and sometimes the cyst is found to have burst, and to have discharged its contents into that cavity. Now if the disease be nearly what I have stated, must not the wound made in the belly, for the excision of the cyst or cysts, always be large enough to admit the surgeon's whole hand? Must it not be often a good deal larger; as when the tumor is large, and composed of a number of bags filled with jelly? Would not such a wound be attended with a good deal of danger from itself? Would it not be very difficult to cut the peduncle or root of the tumor, with one hand only introduced? Would it not be impossible to do this, where the adhesions proved to be considerable? Would there not be great danger of wounding the intestines? If any considerable branch of the spermatic artery should be opened, what could the surgeon do to stop the bleeding? If it be proposed, indeed, to make such a wound in the belly as will admit only two fingers or so, and then to tap the bag, and draw it out, so as to bring its root or peduncle close to the wound of the belly, that the surgeon may cut it without introducing his hand, surely, in a case otherwise so desperate, it might be admissible to do it, could we beforehand know that the circumstances would admit of such treatment. With regard to incisions and suppuration, all that is proposed to be got by this painful operation is the change of the dropsy into an incurable fistula of the belly. For this the patient must not only undergo much pain, but likewise be exposed to great danger; particularly

where the cyst happens not to adhere to the muscles at the part the incision is made, or where there are a number of cysts. In the first case, the wound will be a large one, communicating with the cavity of the abdomen; and both the external air, and the contents of the incised cyst, will be admitted into that cavity, so that we may expect very considerable inflammation. In the second case, where there is a number of cysts, the inflammation and suppuration will either be too slight to discharge all of them, or too considerable to be supported with life."—(Medical Observations and Inquiries, Vol. II. p. 41, &c.) I have quoted the whole passage. The doctor appears to have had a very unfavourable opinion of the operation for the excision of ovarian cysts, and it seems probable that this great man never contemplated the possibility of patients being laid open from the ensiform cartilage to the symphysis pubis, to make room for the removal of ovarian tumors.

I am, sir,

Your obedient servant,

SAMUEL CROMPTON.

January 22, 1844.

CONTRIBUTIONS TO PATHOLOGY.

By JOHN PERCY, M.D. Edin.

Physician to Queen's Hospital, and Professor of
Organic Chemistry, Queen's College,
Birmingham.

(For the London Medical Gazette.)

ADMITTED in-patient of the Queen's Hospital, Dec. 30, 1842, Martha Dickens, æt. 23; single; sempstress. Reports that three months ago, during the presence of the catamenia, she "got wet in her feet," and became affected with pain on the right side of the chest. Leeches and blisters were applied with relief. I also ascertained that for many months previously she had suffered considerable distress of mind. She has never had acute rheumatism. Before admission, she was engaged at the house of my respected colleague, Mr. Lausgton Parker, who informed me that she had had anasarca and palpitation, for which he prescribed a mixture containing digitalis and nitrate of potass.

Present symptoms.—Cough, with expectoration. Faintness, and occasional dyspnoea. Pulse extremely small and feeble, and can scarcely be counted; 88. She is harassed

with frightful dreams. Skin cool. Tongue furred and moist. Perspires much at night. Appetite capricious. Catamenia now present, not having appeared for two months previously. Much complaint of pain referred to lower and anterior part of chest, most severe at a spot on a line with the left nipple, and at the edge of the sternum, aggravated by breathing and coughing.

Both sounds of the heart distinctly audible. Bruit accompanies the first sound, and is loudest two and a half inches below the superior edge of the sternum (the patient being in the horizontal posture). Bruit is heard in the course of the carotids, but is not heard at the apex. Dulness in præcordial region extending over a larger space than natural. Turgescence of the external jugulars, with distinct pulsation. Respiratory murmur generally distinct over the anterior part of the chest.

From the preceding data, I concluded that obstruction certainly existed at the origin of the aorta, and that probably it was dependent upon disease of the semilunar valves. The disease steadily progressed. The pulse at the wrist continued imperceptible for many weeks before her death. Faintness was induced by the slightest exertion. The extremities were constantly cold. She complained frequently of pain referred to the præcordial region and other parts of the chest; of pain also extending down the left arm, and across the forehead. I introduce only a few extracts from my journal.

Jan. 28th.—Last evening, half an hour after tea, she vomited a small quantity of dark-coloured blood.

Feb. 4th.—Shooting pain down both arms. Lightness of head. Nausea after eating. Vomited last evening.

8th.—Since the 6th has expectorated viscid mucus containing pus, and much streaked with blood. Passed blood by stool last night. Shooting pain in lower and anterior part of chest, excited by coughing. Vertigo. Dreams much. Lividity of the tips. Pallor of the countenance, with the exception of the cheeks, which present a flush of pale livid red. Pain in the calves of the legs. Pulse imperceptible. Dulness on percussion over a considerable space on anterior part of the chest. Heart's action very rapid. Turgescence and distinct pulsation of the external jugulars. No œdema in any part.

11th.—Passes blood by stool. Urine scanty. (Edema of feet. Sputum frothy, and streaked with blood.

16th.—(Report of Mr. Fulford, House-Surgeon). The respiratory murmur is loud and harsh in the upper part of both lungs;

inferiorly, there is sub-crepitant râle, most audible on the right side. The first sound of the heart is converted into a rough sawing kind of murmur, loudest at the junction of the third rib with the sternum; the second sound is continuous with the first. The bruit is not so distinct near the apex of the heart. Bruit is heard in the course of both carotids. There is venous turgescence with pulsation. The face is livid and bloated; vision is dim; the lower extremities are œdematous; and there is constant harassing cough, attended with copious thick mucopurulent expectoration mixed with blood.

17th.—The patient has been much disturbed by cough in the night. At midnight there was considerable epistaxis, which relieved the headache. Other symptoms as before.

Feb. 18th.—Countenance much bloated and dusky. There has been some delirium. Epistaxis recurred during the night, and blood of a red colour was also passed by stool.

22d.—Dark ecchymosed patch below each eye. (Edema of legs, but not of arms. Surface of the body generally, especially posteriorly, mottled with livid spots, in many parts resembling *purpura*. Breath continues excessively foetid. Passed blood by stool. Sputum still bloody. Dysuria. Abdomen swelled and tympanitic.

25th.—As before. Extensive dulness over lower part of right side of chest posteriorly; some dulness also on lower part of left side. Mucous and sonorous râles. Complains of a constant salt taste in the mouth; says "it is like salt water running out of the mouth."

She died Feb. 28th, 3 A.M.

Autopsy, the same day.

Body generally anasarcaous.

Chest.—Effusion in the right pleura, but not in the left. Right lung completely condensed inferiorly; condensation apparently of old standing. Left lung small and spongy, and bound down posteriorly by strong cellular bands. I found no trace of hemorrhagic hepatization in either lung.

Heart.—Large; weighed 12 ozs. 5 drs. Troy. Pericardium free, and without effusion. The semilunar valves of the aorta, the mitral and tricuspid valves, were all much thickened at the edges, and had a cartilaginous consistence. No distinct deposit of lymph was observed upon any of them, although their edges appeared to be very delicately fringed. The semilunar valves of the pulmonary artery were perfectly natural. The diameters of these valvular openings were accurately ascertained by carefully distending them with a cone of box-wood, and then measuring the cone with callipers on a line corresponding to the edges of the valves.

Aortic semilunar valves, between $\frac{5}{16}$ and $\frac{7}{16}$ inch.

Mitral $\frac{1}{3}$ of an inch.

Length of the opening of the mitral valves, when the edges were approximated, measured from the auricle, $\frac{1}{16}$ inch.

Pulmonary semilunar valves, $\frac{3}{4}$ inch.

Tricuspid, $\frac{1}{16}$ inch.

Left ventricle dilated; walls an inch in thickness.

Right auricle much distended, and contained a loose clot, with small clots of fibrin entangled amongst the muscular fibres. Right ventricle dilated, but the walls were not increased in thickness.

Aorta a little dilated above the semilunar valves, without asperities on its internal surface. Abdominal aorta contracted; diameter, three inches above the bifurcation, was $\frac{5}{16}$ inch.

The apex of the heart pointed between the sixth and seventh ribs.

Abdomen.—Stomach and intestines contracted, healthy in appearance. No indication of disease in the other organs.

Examination of the Urine.

Feb. 1st.—Dark brown; sp. gr. 1027°; copious pale brick-red precipitate of urate of ammonia; filters clear; turbid by boiling; turbidity not removed by nitric acid, which occasions immediate separation of flocculi.

15th.—Sp. gr. 1025°; similar to the preceding; beautiful pale reddish-brown deposit of urate of ammonia left on the filter.

Analysis of 1000 grains.

Water	944.8
Urea	12.3
Albumen	1.6
Fixed salts	9.6
Organic matter, including uric acid and a very large proportion of colouring matter	31.7
	<hr/> 1000.0

[Chlorine was entirely absent from the fixed saline ingredients of this specimen of urine; nor did I satisfactorily detect soda, although potass was abundant. I repeated the examination with the greatest care, and with the same results. I operated upon the incinerated residuum of 250 grains of urine. Not the slightest trace of precipitation was produced by the addition of nitrate of silver and nitric acid. I obtained, by the addition of carbazotic acid, crystals of carbazotate of potass of the characteristic form; the next morning they were nearly an inch in length. There was immediate precipitation on the addition of chloride of platinum.

Dr. Prout remarks that, "in some instances, indeed in all instances in which I formerly made the experiment, I found the quantity of muriatic acid exceedingly diminished, and sometimes even almost en-

tirely wanting, in the urine of persons in the last stage of chronic diseases, and at the point of death." (On the Stomach, &c.) Becquerel (*Sémciotique des Urines*, p. 85) asserts that this statement of Dr. Prout is entirely without foundation. I am not prepared at present to speak decidedly on this point; I can, however, affirm that, in the case before us, no chlorine existed in combination with a fixed base in this urine. I regret that I did not search for the presence of chlorine in the urine itself, as well as in the residuum of the incineration. The specimen which I subjected to analysis was passed Feb. 15th, and the patient lived until the 28th. On the 25th we find, by reference to the register, that she complained much of a salt taste in her mouth, as though "salt-water was running from it." The coincidence between the absence of chloride of sodium from the urine, and its presence in increased proportion in the saliva, would be remarkable.

Obs.—The symptoms which existed in this case are clearly explained by the post-mortem examination. The extremely constricted condition of the opening through the semilunar valves of the aorta was, probably, the principal cause of the bruit, which, it will be remembered, was loudest in the situation of these valves, was heard in the course of the carotids, and was either absent or not distinctly heard at the apex. The connection between the symptoms recorded in the preceding history, and the diseased condition of the valves, is so obvious, as not to require, in a communication of this kind, further comment. One point is deserving of especial notice, namely, that the disease could not, by careful inquiry of the patient, be traced to rheumatic endocarditis. Her illness evidently commenced with an attack of pneumonia of the lower part of the right lung.

In respect to treatment, palliative measures could alone be resorted to. The almost imperceptible pulse at the wrist, the occurrence of faintness on the slightest exertion, and the languor, of which the patient greatly complained, suggested the exhibition of diffusible stimuli and light tonics accordingly, mixtures, containing ammonia, æther, camphor, calumba, with morphia or tincture of conium, were prescribed with temporary relief. The bowels were regulated by the common oloecynth, or compound rhubarb pill. The patient complaining much at one period of her illness, of pain referred

to the lower and anterior part of the chest, the application of a blister to the sternum was attended with benefit.

[To be continued.]

CONTRIBUTIONS
TO
ANATOMY AND PHYSIOLOGY

BY ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

[Continued from p. 371.]

On the Corpus Luteum.

It has been already stated by me, in some prefatorial remarks appended to Part II., that my brother, Mr. F.J. Knox, who assisted me in most of my inquiries and researches, objected to the analysis I had made of the "Lecture on Generation," by Sir E. Home. I requested him, therefore, to draw up his own views on the matter. These will be found in the following section, which exclusively belongs to him. It was written nearly four years ago, and I now publish it without any alteration or amendment.

I shall only here further observe, that since reading it I have again looked into the "printed catalogue of the Hunterian museum," and regret to say that I see no reason for altering the opinion I formerly entertained regarding it; viz. that it gives no clear idea of Mr. Hunter's labours, nor of his preparations; that it is, in fact, a catalogue of a museum not strictly "Hunter's," but a mixed "collection" from many sources; and that the language employed is calculated generally to misrepresent, unintentionally no doubt, many of Hunter's views. With respect to the preparations illustrative of the history of the corpus luteum, the truth seems to be that the histories of most of them have been lost, or were destroyed by Sir E. Home; and they have been re-described by others entertaining views quite opposed to those of Mr. Hunter. The reader will be pleased to remember what I have already stated on this point, namely, that a few weeks before the appearance of the printed catalogue I examined this very division of the museum, with the MS. catalogue of Mr. Hunter in my hand, kindly sent me by the Con-

servator, and of sixteen preparations evidently bearing on the history of the corpus luteum, I did not find one whose number or label corresponded with the catalogue; or, in other words, the number of the preparation being referred to in the catalogue gave a description altogether at variance, and sometimes ludicrously so, with the preparation itself. Under such circumstances, it is not to be wondered at that the printed catalogue of "the Museum of the Royal College of Surgeons in London" is not what the public probably expected it to be, a catalogue of Mr. Hunter's museum, illustrative of his views and labours, solely. Such a work is still to make.

A single word with reference to "the Lecture" by Sir E. Home, which has given rise to so much dispute and discussion. Like all his other lectures, the substance or pith was mainly copied simply from Mr. Hunter's MSS.; indeed, he says so himself; but his object being fraud and concealment, Sir E. has mingled up many of his own notions, whether original or borrowed does not matter, with those of Mr. Hunter. Hence has arisen the inextricable confusion so remarkable throughout all these lectures, a confusion which long puzzled myself, and which I find greatly embarrasses foreign scientific men: such is the mixture of those observations of the highest and most transcendental merit which of course he drew from Mr. Hunter's writings, from his preparations, and from Mr. Cliff's recollections, with those hasty, and but too often crude conjectures more particularly his own.

To conclude:—On re-examining Sir E. Home's "Lecture," I find the following passage, p. 295, immediately following the announcement of what Sir E. considers and calls *his* new doctrine, though one of the oldest in physiology, namely, that "the corpus luteum is a glandular structure forming the ovum, whether the ovum be impregnated or not."

"This new (!) fact led me to examine the ovaria in the preparations in this collection (meaning, of course, Mr. Hunter's museum), both in women full grown and just arrived at puberty, in which the hymen was entire; in many such ovaria the corpus was distinctly seen."

Now between the servant maid's case, and this *new fact*, as Sir Everard is pleased to call one of the oldest of physiological theories, there absolutely is not the slightest traceable connexion; but it suited his purpose to say so, and it enabled him to go back to the museum, as many do yet, to pretend to look for confirmation of the fact, as he terms it, in preparations which they would fain make believe were put into the museum by Mr. Hunter merely by accident; in fact, that he placed them there, as modern collectors do, without any reference whatever to what they may illustrate, but merely as so many preparations. But virgin, or presumed virgin ovaria, presenting the appearances of corpora lutea, could have been placed by Mr. Hunter in his museum only with one view, namely, of proving the corpus luteum to be a structure independent of impregnation: thus this *new fact* of Sir Everard's was at least as old as Mr. Hunter's preparations, but was, in fact, a hundred years older than Mr. Hunter himself.

The plates referred to by Sir Everard as being drawn from preparations of virgin ovaria, shewing a corpus luteum in "the collection," are 108, 109, and 110. Now, on looking at these plates, I find that plate 108 represents a case of ovarian pregnancy, and therefore has no connexion whatever with the subject in question: this is in Sir Everard's usual style. Plate 109 gives six views of ovaria; the 1st and 2d are from a woman who carried a child at full birth; the 3d and 4th are from the same person; and the 5th and 6th represent the ovarium of a woman who died at the age of 70, to show how little of the appearance of corpora lutea remains. Sir E. then refers to these plates as representing the ovaria of adult women in whom the hymen was entire, and who had corpora lutea in them! virgin ovaria! of whom one had given birth to a child! Yet such was the state of science in Britain at the time these papers were read in London to the Royal Society, and before the united College of Surgeons, that no one was able, or had courage enough, to face the clique of the Society, and to denounce the author and his abettors for what they really were—impostors!

But to proceed. It is scarcely necessary to say that plate 110, the one next

referred to by Sir Everard, has no connexion whatever with the text; it does not represent virgin ovaria, but human ovaria five days and six weeks after impregnation.

The next passage in the text which refers to the matter now discussed is as follows: "That corpora lutea are formed in a state of virginity, is proved both in the human species and the hog tribes, as will be ascertained by the following examinations."—Plates 108, 109, 113, 114, p. 304.

I have already shown that plates 108 and 109 have no connexion whatever with the matter treated of in the text; plates 113, 114, and 115, refer exclusively to the ovaria of the pig and of the cow; but the description opposite plate 113 distinctly says that the ovarium here represented is the "external and internal view of an *impregnated* (not a virgin) ovarium: so that of all the boasted proofs of the *new fact*, we are at last reduced to the contents of plates 114 and 115, to which he has not referred: these plates refer exclusively to the pig and the cow: they purport to be drawings of the ovaria in a virgin state at six months; perfect corpora lutea may be seen in them at all stages. The preparations from which these figures are taken must at one time have existed in the Hunterian museum; but if so, why are they not described in the printed "Catalogue of the College?" They were Mr. Hunter's, evidently, and they mark in a peculiar and forcible manner the theory he held in respect to the formation and functions of the corpus luteum.

Lastly, at page 304, the case of a young woman is referred to, 20 years of age, with a perfect hymen, in whom one of the ovaria was found to contain a corpus luteum and an ovum. Plate 110 is referred to; of course the drawing has no connexion whatever with the text.

The ovaria in the adult but virgin state are egg-shaped bodies, compressed from before backwards, of a pale red colour, wrinkled and rough at their surface, which often presents a kind of cicatrice. They are placed in the substance of the broad ligament of the uterus, attached internally (towards the median plane) to the uterus by a small filamentous cord about $1\frac{1}{2}$ inches long, entirely solid, and called the ligament

of the ovary (*ligamentum ovarii*), and externally to one of the fimbriae of the uterine tube (*tubæ Fallopiæ*, *morsus diaboli*).

Dissection proves them to be composed of a soft and spongy parenchyma (*stroma*—Baer), which, when torn, seems composed of cellular and vascular lobules of a greyish colour, gorged with a great quantity of fluid. This parenchyma (*stroma*) is enveloped by a dense cellulo-filamentous membrane (*tunica albuginea*), from the inner surface of which there pass a great number of prolongations into the stroma. The arteries (named spermatic) which supply the ovaries with arterial blood, arise from the anterior and lateral parts of the aorta, a short way below the renal arteries; they anastomose with the uterine arteries. The veins commence in the ovaries, and, after a very complex course, terminate; the right in the vena cava, the left in the corresponding renal vein. The nerves (named spermatic) consist of two plexuses, derived chiefly from the renal plexus. They follow the course of the spermatic arteries; the filaments are extremely fine, and have not been traced into the texture of the ovaria. These textures reach and leave the organ at a transverse line, which may be called *fixed*, placed inferiorly and posteriorly between, in fact, the layers of the peritoneum, the ovaria rising, as it were, angularly, and looking upwards from off the anterior lamina of the broad ligaments. Lastly, the organ receives an almost complete envelope from the peritoneum. The broad ligaments of the uterus are known to be two folds of the peritoneum reflected off the anterior and posterior surfaces of the uterus. The vessels, &c. passing towards and from the uterus and ovaria are placed between these laminae, and the ovaria also lie between them; these bodies project anteriorly by the anterior peritoneal fold, having, as it were, been pushed before the ovary; so that the organ may be said more properly to derive its peritoneal tunic from the anterior lamina of the broad ligaments: this seems rather an important fact, as it influences the position of the ovaria, more especially when the whole genital organs are spread out on a flat surface.

Ovarian vesicle.—In the midst of the stroma, or parenchyma of the ovaria, are lodged small vesicles, to the num-

ber of from 15 to 20, transparent, of the size of a millet-seed. They are composed of a very delicate pellicle, or covering, containing a viscid fluid of a reddish or yellowish colour, and around these vesicles the vascular ramifications are more numerous and more minute.

We shall here record the dissection of the human virgin uterus and ovaria, as a guide to future observers, and a standard to sundry weights and measurements, which we shall give, as connected with impregnation.

The virgin female uterus perfectly healthy. The broad ligaments were divided with a pair of scissors all around the uterus, and removed, including the fallopian tubes. The vagina cut across close to the os uteri :

Weight	470 grs.
	Inches lines.
Length mesially, os uteri to fundus	2 3
Greatest transverse breadth, near fundus	1 6
Antero-posterior breadth	0 9

This uterus had been many years in alcohol, having been put up as a specimen of the unimpregnated healthy female uterus, being that of a young person, æt. 18, and who had most assuredly never given birth to a child.

Right ovarium—weight	78 grs.
	Inches lines.
Length of the fixed margin	1 3
Greatest depth	0 8
Greatest breadth	0 4

Section along the fixed (straight) margin, that is between the two laminae of the peritoneal tunic, where the vessels enter the organ. The external surface of this ovarium is marked with numerous pretty deep waving fissures, the effects, as I had always supposed, of being put amongst alcohol, but which I find anatomists call cicatrices, a term to which they must have applied no positive meaning, as they use the same word, without any qualification whatever, to an appearance presented by the section of some impregnated fruitful ovarian vesicles (Graafian vesicles after fruitful impregnation, corpora lutea, &c. &c.)

The section displayed four cysts, varying from one to three lines in diameter, and composed of a distinct and apparently loosely connected capsule, in the interior of which a shrivelled-up body lies; these appear to me the remains of ovarian vesicles.

Left ovarium—weight	80 grs.
	Inch lines.
Length of fixed margin	1 6
Greatest depth (about middle)	0 9
Greatest breadth	0 4

Section along the free convex margin, carried so deep, and in such a direction, as nearly to divide the ovarium into two equal halves. This ovarium weighed two grains more than the right, and felt fuller and firmer. The section was made along the free convex margin (by much the best), and displayed eight distinct cysts, which the knife had nearly bisected, with others of a smaller size, in which the knife had removed only a small part of the capsule. The largest of these cysts may be about two lines diameter, and they are all composed first of a capsule of about a quarter of a line thick, loosely connected with the stroma of the ovarium, and in the interior, lying shrivelled up, a small body perfectly loose. The capsule I consider the external membrane of the unimpregnated ovarian vesicle; the loose body I consider the membrana granulosa, and its fluid now absorbed, or the granular membrane itself contracted. What are these cysts, then? My opinion is, that they are ovarian vesicles unimpregnated, in a state of active preparation at the time of death.

Uterus of a married woman who had had two children, besides miscarriages. This person put a period to her existence by cutting her throat. Her husband, who had been a letter-carrier, but unable for the work, had died the morning before from sheer starvation. The texture of the uterus, when cut into, seemed more than usually vascular. (Same dissection as in the former case.)

Weight	8 oz.
	Inches lines.
Length from os uteri to fundus	2 10
Greatest breadth near fundus	2 1
Antero-posterior diameter, or thickness	1 6
Right ovarium. Weight	65 grs.
	Inch lines.
Length	1 5

Form—an elongated compressed oval, externally presenting a mottled appearance, with three or four irregularly-shaped grooves, or fissures (*hacks*). A section in the long axis displays, amongst other appearances, two cysts bisected; the one nearest the proximate pole of the ovary has a thick, distinct, whitish capsule, containing nothing;

the other, below, or outside of it, appears to me more a cavity in the ovary. I observe two vesicles (Graafian) about the size of peas, containing a fluid.

Left ovarium (weight 74 grs.) presents externally a diseased mottled appearance, with numerous hacks towards its distal pole. A section displays in the upper (proximal) end of the ovary two white tubercular-looking masses, a very distinct melanotic mass, and, as it seems to me, more numerous blood-vessels than usual. The fimbriated extremity is evidently altered by the formation of adhesions, but the tube is quite pervious. It appears to me that the fimbriated extremity is calculated and formed to embrace entirely the ovarium, and I strongly suspect that the seminal fluid reaches the organ. In both these ovaria I observe distinct vesicles, similar to what may be observed in the sheep, but smaller in size, not exceeding two lines in diameter; they are quite near the surface, being covered only by the semi-transparent peritoneum: these did not seem to be very vascular.

The examination and comparison which I have drawn between these two cases seems to me interesting. In neither case was there the slightest approach to uterine action, particularly ovarian. The increase of weight in the uterus of the female who has had children seems enormous, being more than eight times that of the virgin, whilst the virgin ovaria are both considerably heavier (nearly 10 grains,) than those of the married female.

We cannot call the attention of our readers in too strong language, to the fact, that in this part of our "contributions to the history of the corpus luteum," we confine our views and observations entirely to human structure.

That vesicles exist in the virgin state, dissection proves beyond a doubt, and although there may be considerable discrepancies or differences in the anatomical description of these vesicles by various authors, yet, upon the whole, that given by De Graaf may be taken, and which we have already given, it being merely copied by all anatomists.

Does the vesicle undergo any changes in the virgin state? This will be found by no means answered; and yet it is unquestionably the most important question which the whole subject of

pregnancy, and all its phenomena, present. Volumes have been written by numerous authors on the subject of generation, and this amongst other questions has become involved in the greatest possible confusion. The term false corpora lutea (in contradistinction to true corpora lutea,) appears in every second line of some late authors; and cysts, hydatids, melanotic tumors, effusions of blood, &c. &c. &c. are spoken of as being present in nearly every case! It is admitted at the same time that these appearances often present a striking resemblance to the true corpus luteum; by which expression is now very generally meant an appearance in the ovarium of a woman who either is at the time impregnated, or has very recently had a child; a change, in fact, which is effected on the ovarian vesicle by impregnation, or co-exists with it, or immediately precedes it.

The term corpus luteum is rather an unfortunate one; but it will not now be easily changed. It appears originally to have been given by the early observers to a yellowish body found in the ovaria of the lower animals, and when so applied it is very appropriate; but when extended to the human subject it leads to great confusion. Part 1st of these our contributions will be found nearly composed of the history of one case, and the anatomical description of the so-named corpus luteum. The body in the human ovarium known under the name of a corpus luteum is of an irregularly spherical or oval form, and of a very complex structure, consisting of many parts and textures, tunics, and cavities, and these ever undergoing changes according to the period of impregnation. The distinctive characters proposed by some authors, in order to determine between what they call true and false corpora lutea, are extremely finely spun, and in fact, in the present state of our knowledge, there are, perhaps, no two persons living, who will agree upon any case which may be brought forward. It is all very easy in a case where a fœtus is found in utero; but shew a man, however high his standing may be, the ovary alone, and a thousand to one he will have nothing but mere surmises and guesses to offer.

The recorded opinions of authors, of

which we shall immediately quote a few, will illustrate how much Doctors differ on this important point. There are some, we may remark, who think that ovarian inflammation always follows impregnation, and according to them disease and diseased appearances in the ovary are universal! This is most assuredly not in unison with the ordinary laws of nature, and, we feel convinced, will not in any shape be borne out by a scientific appeal to the structure itself. We think that disease and inflammatory action in the ovaria is, perhaps, the rarest possible appearance, and that the statement is made by those persons merely to get over facts of which they know nothing.

[To be continued.]

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

The Medical Student's Guide and Almanac for 1844: the latest Regulations of all the Licensing Medical Corporations in the United Kingdom, with a Correct List of their Officers; the Metropolitan and Provincial Schools, and Universities and Medical Schools of France, and brief Notice of the German Universities; and a great variety of useful information. Renshaw.

The Medical Almanac: a Calendar of Medical Information for the Year 1844, being Bissextile or Leap Year. Churchill.

EITHER of these brochures will be found very useful by the medical student or practitioner. Renshaw's has the advantage of containing most information; Churchill's the recommendation of being cheaper. (The price of the former is 2s. 6d.; that of the latter only a shilling.)

The latter contains every thing in the world connected with physic and surgery which this country can boast; the former every thing to be found both at home and abroad, giving us pretty full information regarding the universities and medical schools of France, and all that is necessary to be known touching those of Germany.

We advise our medical friends to have one or other of these almanacs on their library table.

MEDICAL GAZETTE.

Friday, February 2, 1844.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

GENERAL PRACTICE.

To clothe the naked is pretty generally recognized as a social duty; but there are two modes of performing it which are adopted by those who give themselves the trouble of relieving this form of human suffering. The one is that detailed in the well-known legend of St. Martin. The saint, meeting a naked beggar, drew his sword, and divided his own mantle into two equal portions, one of which he gave to the sufferer. That is one way. Hume the historian quotes from Fitz Stephens an anecdote of Henry II., who, “when riding with his Chancellor and then favourite Thomas-à-Becket, met a beggar shivering with cold. ‘Would it not be very praiseworthy,’ said the King, ‘to give that poor man a warm coat in this severe season?’ ‘It would, surely,’ replied the Chancellor, ‘and you do well, sir, in thinking of such good actions.’ ‘Then he shall have one presently,’ cried the King: and seizing the skirt of the Chancellor's coat, which was scarlet and lined with ermine, pulled at it till the Chancellor, to avoid a tumble, let go his coat, which the King bestowed on the beggar, who being ignorant of the quality of the persons, was not a little surprised at the present.”

This last is unquestionably the more royal method of the two—it is also the more popular; and the one to which men are very apt to resort in redressing grievances. In our meditations on the inconveniences which beset the general practitioner at this moment, the royal method of relief has been suggested to us, and has found some favour in our eyes. The person

at whose cost we are most tempted to be benevolent is the retail chemist and druggist; and the same kind of motive prompts us as tempted the monarch to exercise his jocular benevolence at the expense of his Chancellor, namely, that he seems so well able to afford it. The smart shops and the splendid bottles of the druggist are as suggestive as the scarlet of the well-mounted churchman.

The College of Physicians has really imitated, in some degree, the good St. Martin, in whose parish they are located. If they have not equally divided the mantle of their honours with all who desired to share it, they have at least thrown the skirts of it over many who were formerly naked, and though some begged somewhat sturdily to be sure, yet merit will be claimed and must be granted for the concessions made.

It is quite notorious that the profits of the general practitioner are gradually falling into the hands of the chemist and druggist. We pointed out in a late article some of the principal circumstances which had produced this effect*, and we should now be glad to see things a little set to rights.

And first a few words about the retail druggist, at whose coat we are going to have a pull. The character of the druggists, as a body, we believe to be excellent. We well know that half a century ago, or less, there were but a few houses where genuine drugs could be procured, at any price. The names of W. Allen, Savory, Fisher, Godfrey, and a few others, were a guarantee that at their houses the right thing would be given for the right price, but in all shops except the well known few, the obtaining a genuine article in a good state could not be relied on, and even at some of these, the more expensive drugs, such as Peruvian bark, were kept of various qualities and at different

prices. Systematic adulteration, we are credibly informed, was habitually resorted to, and the confining this within certain well-known limits was a mark of respectability; to overpass these limits only was disgraceful. "There is lime in this sack, too," says Falstaff, wounded in his tenderest point. "Things that are mouldy lack use," was the witty knight's excuse for enlisting the lean tailor instead of sounder men; and some drugs that ought to be thrown away are kept, no doubt. There is much Devil's dust in all trades, that Mr. Ferrand has not yet beaten out, and never will. But, making the due allowance for human frailty, we believe that the drugs at most retail shops are genuine.

How, then, is the abundant and ever-increasing display of plate glass, mahogany, and coloured lights, paid for? Simply by profits, half at least of which ought to accrue to the general practitioner. The charges for drugs, when compounded, are exorbitant. They are charged at a price which was once supposed to be that of intelligence and learning in prescribing, not merely of honesty in supplying and care in compounding the drugs—not of so much dog latin as will translate a prescription, but of so much skill and responsibility as will contrive one. *Hic labor hoc opus est.*

If the evil stopped here, if there were merely a rivalry between the attractive shop of the druggist, and the somewhat more dignified seclusion of the qualified apothecary, the case would be comparatively simple—there would be a serious pecuniary loss to the latter, it is true, but that would be nearly all. Even the iniquities of unlicensed counter practice might then be left to the watchfulness of professional jealousy, acting through the coroner or the Common Pleas, as the case might be.

But the evil is far more complicated, and involves the whole character of a respectable branch of the profession,

* See MED. GAZ. p. 250, et seq. of the present volume.

and that the largest. Well-educated men are tempted to rival the retail druggist, and to court both custom and practice by all the arts of display which the latter finds so successful.

The public, especially the lower classes, see no difference—hardly a patient comes to us without having tried what a “chemist” could do for him; and the vexatious part of the business is, that when we gently chide him for not going at once to a qualified practitioner, the chance is that he shows us a bottle or a pill-box with the name of a licensed man emblazoned on it—an M.R.C.S. or a licensed apothecary.

It is quite true a diploma or diplomas may have been hung up in the shop, but the chances are, that, if noticed at all, they were taken by the customer patient for a specimen of marking ink, or the advertisement of some patent medicine, with the seals and signatures of respectable witnesses to its efficacy. We *have* made such a mistake, and then been shocked at seeing the arms of the Royal College, the rhinoceros of the Worshipful Society, or their no less respected figure of Apollo astride of the Python; so apt are we to judge of a man or of a diploma by the company we find them in.

We formerly shewed that the general practitioner, the apothecary of former days, laid the foundation of druggistry, now so flourishing, by his own mode of charging for medicines. This mode of payment is now felt to be absurd and inconvenient; but if it can be proved to have entailed positive loss, it will be abandoned by all. It has been abandoned by many from a mere sense of its unfitness and inexpediency, and the false position in which it places them.

But it is hard that high-minded and conscientious men should lose the reasonable profits of the art they have studied faithfully, and it is grievous that others should drag down with them the whole body to which they belong

by a ruinous competition with the retail druggist.

It is well known that a bill is to be brought forward this session by Sir J. Graham for the better regulation of the profession, but it is to the acts of individuals, not to Acts of Parliament, that the profession must trust for reform. The Apothecaries' Act of 1815 gave the Company much power; but what good has it done them? The power thus given was two fold: that of prohibiting the practice of pharmacy without their license, and that of exacting their own qualifications for obtaining such license. The first they used not against their real rivals, the retail druggists, who prescribed, and who thereby became the enemies of the state, and proper subjects for coercion, but against their apparent rivals, the surgeons. The second power committed to them, that of fixing their own standard of qualification for license, they have used well indeed for the public, and laudably for their own reputation; but while they have raised the standard of qualification, the low practice of remuneration for drugs is continued; their licentiates are like flying fish, they soar for a time in the higher regions of science, but are fain to return for nourishment and support to the lower element which they have quitted. Like this unhappy fish, too, their enemies are both above and below them.

Now if, like Henry II., we were disposed for a benevolent frolic in the capital, we would incontinently do something of this sort:—We should say to the Worshipful Society, give up your Hall at Blackfriars, with all its stock and fixtures at a valuation, to the Pharmaceutical Society. Let the Pharmaceutical Society appoint or license its members to open shops in various places*, let the practitioners of each dis-

* The Pharmaceutical Society professes, we believe, to expel such of its members as pre-

trict open accounts with the different shops, and have their medicines made up at cost price, or a little above it. Let them charge so much a visit, and give the medicines in. The public would be better physicked, for the shops would be all first-rate, and the management liberal. The practitioner would come home, and, first sending or taking his prescription to the shop, he would go quietly to his studies, or his nap, without the anxieties of assistants, porters, and other nuisances.

The public might still humour their own fancies by buying what drugs they liked; but, instead of irresponsible counter practice, there might be a qualified man always on duty for consultation, as well as a first-rate tradesman for the sale of drugs. A really scientific chemical staff would be at hand, with all appliances and means to boot, for the delicate operations of experiment or analysis: in fact, the advantages would be so numerous, that to detail them is impossible. But hold; while we are pulling at the imaginary Chancellor's coat, we are warned to dismount from our own hobby. We may take another airing, however, on a future day.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

Tuesday, January 23d, 1844.

JAMES COPLAND, M.D. F.R.S. IN THE CHAIR.

Abstract of a Case of Phlegmasia Dolens and Synovitis. By THOMAS MAYO, M.D. F.R.S. &c.

THE train of symptoms described in this case commenced about five weeks after delivery, in a healthy female, aged 24, whose lochia, after the delivery, had been nearly suppressed.

The first symptom was lameness, for which she was placed in the surgical wards of St. Marylebone Infirmary. Abscess at the knee then was observable; the thigh swelled; and phlebitis of the femoral vein was next noticed. The phlebitis was sub-

dued by antiphlogistic treatment, and the knee freely punctured, with much discharge of pus, and subsidence of pain and fulness. Inflammatory cerebral disease next became manifest; and, on this yielding to depletion, moderately performed, a painful and highly congested state of the conjunctiva ensued. Hemiplegia now occurred, with very defective articulation. Of this class of symptoms, the first set yielded rapidly to remedies; the latter is still, in some degree, present. Strychnia seemed now to benefit the patient.

Throughout this illness, the presence of a hysterical diathesis was highly observable. The author takes occasion to notice, that this fact, coupled with the varying and Protean nature of the symptoms, might have seemed to justify the practice appropriate to hysteria, but for the presence of well marked inflammatory symptoms; and he draws some practical inferences from this consideration, as to the means of preventing such mistakes.

Account of a Horn developed from the Human Skin; with Observations on the Pathology of certain Disorders of the Sebaceous Organs. By ERASMUS WILSON, Esq. Consulting Surgeon to the St. Pancras Infirmary.

Investigating the pathology of the sebaceous organs, the author observed, that several disorders of these organs were due to alteration in the qualities of the sebaceous secretion. This secretion is separated from the blood through the agency of the cells, found upon the internal surface of the glands, and contains among other substances an albuminous fluid and calcareous salts. When the albumen is in larger proportion than natural, the cells retain their distended form, and by accumulation produce those small tumors which are termed *mollusum contagiosum*. When the calcareous matter is in excess, and remains in the flattened cell, the accumulation of these cells constitutes the calcareous sebaceous tumors. In other cases the sebaceous cells from torpidity of the skin accumulate in considerable quantity, and give rise to small sebaceous tumors. The peculiar pathological character of these tumors is their laminated texture, and the identity of structure of their contents with epidermis, most if not all of the peculiar constituents of sebaceous substance being absent. When the contents of such a tumor as this are extruded from the mouth of the follicle, and become desiccated, they form a hard, laminated, semitransparent mass, identical with horn. A horn of this kind was removed by the author from the thigh of an aged female; it had been some years in growing; it was two inches and three quarters in length by two inches in greatest breadth. The horn was laminated longitudinally, and

scribe or practise medicine: is this acted on, or is the misdemeanor never committed?

towards the apex was split in the direction of thin laminae. In minute structure it was composed of flattened epithelial cells, closely condensed, and in some parts having a fibrous arrangement. The cells measured in length $\frac{1}{300}$, and in breadth $\frac{1}{400}$ of an inch, average dimensions. Chemical analysis of horn shews it to consist of albumen, mucus, phosphate of lime, chloride of sodium, and lactate of soda. The author has collected ninety cases of horn, the majority of which occurred in the female subject. Among the older writers horn was a subject of curious speculation. Rhodius met with a Benedictine monk who had a pair of horns, and was addicted to rumination; and Fabricius having seen a man with a horn growing from his forehead whose son ruminated, attributed the peculiarity in the latter to the ruminant character of the former. The most remarkable case of horn on record is that of a Mexican porter, in whom the horn was fourteen inches in circumference around its shaft, and divided into three branches. The author concluded by advertising to the authors on this subject, among whom are Vicq d'Azyr, Sir Everard Home, Alibert, Rudolphi, Cruveilhier, Sir Astley Cooper, and Mr. Travers.

The next meeting will be held on Tuesday, the 13th February, 1844.

ROYAL MEDICO-BOTANICAL SOCIETY.

DR. COOKE IN THE CHAIR.

AFTER reading the minutes of the preceding meeting, Dr. Houlton submitted a long and very interesting paper on Hyosciamus, tracing its use in earlier times, describing the various plants now met with by the pharmaceutical chemist, and concluding with a definition of the characteristics required to distinguish those plants offered as hyosciamus, but which possess but little narcotic power, from the genuine and medicinally useful plant. It would be utterly impossible for us to do justice to Dr. Houlton's paper by a mere abstract; its value consists in the fulness of its details: we therefore proceed to notice some specimens of various fruits and seeds which were laid before the meeting by Mr. Mowbray.

1. *Algarrobas, Carouga, fruit of the Carob Tree, or St. John's Bean (Ceratonia Siliqua, L.)*—Mr. M. observed that the tree which furnishes this fruit flourishes perhaps in the greatest abundance in Spain, where the fruit is used for fattening cattle, pigs, &c. On the shores of the Mediterranean it is also found; but an absurd prejudice to the effect that it is injurious to the neighbouring crops has caused its destruction to a very great extent. Its value has been

demonstrated to the inhabitants of Spain during recent events; for during the siege of Barcelona, thousands of the emigrants found a ready food in this fruit, on which many of the lower classes almost entirely subsisted. The specimen submitted to the meeting was picked up by one of those restless and indefatigable travellers, an English merchant, to whose utilitarian views it seemed to offer some allurements, and, together with some more of the same kind, found its way to Mr. M.'s laboratory, with a view to ascertaining the purposes to which it might be applied. By crushing under eage stones, and sifting, the saccharine pulpy interior may be separated from the husk and seeds; subsequent infusion of this powder in cold distilled water, and evaporation, furnished nearly 30 per cent. of an excessively sweet uncrystallizable sugar mixed with gum and a little albumen. The liquor, previous to evaporation, by treatment with nitric acid, gave very well-defined crystals of oxalic acid; and to this manufacture it has been applied on a large scale with much advantage.

Mr. Mowbray next drew the attention of the meeting to some of the seeds of the *Sesomum orientale*, the source of the oil now found in the shops of some druggists under the title of nut oil, arising, perhaps, from a desire to conceal the true origin of this oil, and fairly applicable to it if taste alone were the authority in such matters. This oil is referred to in some works as teal oil, and has been mixed by some druggists with the expressed oil of almonds. The seeds are shipped to this country from the East Indies.

Specimens of the marking nuts of India were next submitted to the meeting by Mr. Mowbray. These nuts are used in India for marking linen, cotton, &c. By cutting the fruit in two, there is found in the interior a kernel, surrounded by cells containing a jet-black liquid of an astringent taste: this liquid, or natural ink, is used by the natives of India for giving an indelible stain, as above observed, to linen and other fabrics.

Seeds of the *Gossypium arboreum* (cotton seeds) were next laid before the Society as being interesting chiefly to the pharmacist, from the fact of their furnishing to the American market an oil wherewith castor oil is much adulterated in the States, and also as a ready means of rendering, by admixture merely, the solidifiable balsam copaiva of Para, S. A. nonsolidifiable.

Much interest was excited by the specimens referred to; and a vote of thanks awarded, in the usual form, to Dr. Houlton for his valuable paper, and to Mr. Mowbray for the interesting specimens and particulars relating thereto, which had been submitted to the Society, after which the meeting separated.

ROYAL COLLEGE OF SURGEONS.

A MEETING was held at the Crown and Anchor Tavern on Monday, the object of which was to take steps for opposing the operation of the Charter lately granted to the College of Surgeons. It was attended by the same class of members, and the various resolutions were brought forward by the same parties, who for some years have taken the most active part on such occasions. As, however, we may be suspected of not being quite impartial on this question, we subjoin a report of the proceedings which appeared in the *Times* of the 31st, and which it will at once be perceived comes from some friendly hand.

A public meeting of the medical profession was convened on Monday evening, for the purpose of considering what steps ought to be taken to resist the aggressive clauses contained in the recent charter of the College of Surgeons of London. The meeting was held at the Crown and Anchor, Strand, and was numerously attended by a body of highly respectable and influential members of the medical profession. Among others present, we noticed Drs. Lynch, Wilson, Mackenzie, Tyler Smith, Mr. Carpue, Mr. W. Harvey, Mr. Ancell, Mr. Borthwick, Mr. Macilwain, Mr. Leeson, Mr. Dermott, Mr. Rug, Mr. Cooper.

Mr. Macilwain took the chair, and after opening the meeting with a neat and appropriate speech, called upon Dr. Lynch to move the first resolution.

Dr. Lynch considered that Sir J. Graham was much to blame for having recently conferred a charter upon the College of Surgeons, without consulting the wishes of the great body of the medical profession. Dr. Lynch entered at some length into the subject of the neglect which several distinguished members of the surgical profession had experienced from the council of the College. Among others, he particularly recognized the late Mr. Brooks, who was ruined by the council of the College having passed his name over, and Mr. Carpue, that "Nestor of modern surgery," who had been infamously treated by that corporate body. The speaker stated that Mr. Carpue would have been present had not indisposition confined him to the house. (At this moment there was a general buzz in the room, and a voice exclaimed, "There is Mr. Carpue.") As soon as he was generally noticed the whole meeting rose, and the cheering was loud and vehement.) Dr. Lynch, in continuation, said, that Mr. Lawrence had at one period of his life denounced in emphatic language the constitution of the College of Surgeons, but that gentleman had abandoned his former

principles, and deserted those with whom he formerly acted in the promotion of the cause of medical reform. (Cheers.) He (Dr. Lynch) admitted that in the list of 300 Fellows recently elected there were some good names, for it was impossible to select from the present body of the profession 300 men without having among them some worthy fellows (laughter); but in the list he saw also the names of many shabby fellows—mere striplings—beardless boys—who certainly had no right to have such an honour thrust upon them. In the list he also saw the names of men whose only claim to the fellowship consisted in their being sycophants to the council—men whose names were to be found upon a brass plate which was placed upon other people's hall doors. Dr. Lynch then referred to the insulting terms which Sir B. Brodie had used towards the great body of general practitioners. Sir B. Brodie had called them "subordinates." That was a gross insult, which no man, whatever his station might be, was justified in using. Dr. Lynch then moved the first resolution, expressive of regret at the delay which had taken place in the progress of medical reform, and pledging the meeting to the adoption of vigorous measures.

Mr. Carpue seconded the resolution. He was much cheered. He considered that the object which the meeting had in view was most important. He had in the course of his life delivered at the least one hundred courses of lectures, and consequently knew experimentally much of the state of the profession. The science of surgery had much advanced of late years. Fifty years ago, he saw one of the chief surgeons of St. George's Hospital occupied one whole hour in performing the operation for the relief of popliteal aneurism—an operation which, in the present day, is performed in three minutes. He considered the conduct of the College in excluding from the council medical men engaged in the practice of midwifery most reprehensible. The man who practises in this department ought to be honoured instead of being degraded. The College of Surgeons did all they could to lower this class of medical men in public estimation.

Dr. Wilson deprecated with much warmth the conduct of the College, and considered that the profession ought to unite to obtain a repeal of the charter.

Mr. Cooper considered that Sir J. Graham, by granting such a charter to the College, insulted the women of England, by degrading those members of the medical profession who practised as accoucheurs.

Mr. W. Harvey, surgeon, Messrs. Webb, Rug, Ancell, Leeson, Dermott, Borthwick, severally addressed the meeting at some length in support of the object for which it

was convened. There appeared to be a spirit of firm but temperate opposition to the charter. No voice was raised in its support. All the resolutions were condemnatory of its clauses. A committee was formed, consisting of the principal speakers, to carry the opposition into practical effect. A deputation is to wait upon Her Majesty's Government on the subject, and members of Parliament are to be requested to bring the matter before the House of Commons.

The meeting did not separate until after 10 o'clock. A large sum was subscribed to defray the expenses, and to carry out the object for which they met.

We observe the following refutation of Dr. Lynch's statement in the *Times* of yesterday:—

To the Editor of the Times.

SIR,—In *The Times* of this day I have read an account of a meeting respecting the duties of the Royal College of Surgeons, in which it is reported of one of the speakers that he “referred to the insulting terms which Sir B. Brodie had used towards the great body of general practitioners. Sir B. Brodie had called them ‘subordinates.’ That was a gross insult, which no man, whatever his station might be, was justified in using.”

I shall feel obliged to you if you will allow me, through the medium of your journal, to state that I never used such an expression on any occasion, and that nothing has been at all times further from my wishes than to depreciate an honourable and independent profession, to whose kindness and favourable opinion I am indebted for so many of the advantages which I have obtained in life.—I am, sir,

Your obedient servant,

B. C. BRODIE.

14, Saville Row, Jan. 31.

LECTURE

ON

ABSCESS AND FISTULA CONNECTED WITH THE RECTUM, AND ON FATTY TUMORS,

*Delivered in the Theatre of St. George's
Hospital, January 17, 1844,*

BY SIR B. C. BRODIE, BART.

Abscesses of the Rectum—continued.

GENTLEMEN,—There are two classes of cases in which there are abscesses in the neighbourhood of the rectum which I ought to have mentioned in the last lecture, and which I shall briefly notice in the present lecture in order to supply that deficiency.

I mention the following case as the first that drew my attention to this particular form of the disease. I was sent for, more than twenty years ago, to a gentleman under these circumstances. For some considerable time he had been suffering pain, deep-seated, in the pelvis; there was then a sense of bearing down of the rectum, and what he called violent painful spasms. It seemed not improbable that these were spasms of the *levator ani* muscle. However that may have been, when I was consulted he had been suffering excessive pain for some weeks (coming and going) in the rectum. On examining the external parts, I could discern nothing; but on introducing my finger I felt a large bulging on one side of the gut, extending up much further than the finger would reach. I introduced a lancet by the side of the gut to that point in which this tumor existed, and when the blade had passed not only to the shoulders but quite up to the handle, there came out a large quantity of pus. I then introduced a probe-pointed bistoury, and laid the whole open into the gut. The incision went a good way up by the side of the gut, and I remember that there was considerable hæmorrhage afterwards, which required the pressure of lint and the finger to stop it. The patient was relieved of all his sufferings, the discharge of matter, however, continuing for a considerable time, but gradually diminishing. I saw him for some months, and at last the discharge of matter altogether ceased. The patient remained well from this complaint, but died of another some few years afterwards. There was no evidence, in this case, that the abscess had any connexion with the rectum, except that which was made artificially. I have seen three or four other cases, but I have only kept notes of one of them, and that was the case of a man who died in this hospital. There had been symptoms of one of these deep-seated abscesses high up by the side of the rectum. It presented itself at last by the side of the anus. The patient died, having other complaints upon him, without the abscess having been opened. On examining the body after death, an enormous abscess was found in the pelvis by the side of the gut, which could be traced up, as we thought, to the fascia lining the obturator muscle, and it appeared to us at the time that it had begun between the laminae of this fascia. No communication could be detected with the gut.

I do not say positively that these cases may not have originated in disease of the rectum, but from the examination of the last case, and from the history of others in which the patients recovered, I am led to think that it was otherwise, and that the disease was merely an accidental formation of matter

in the pelvis which made its way down by the side of the rectum.

Abscesses may form in the neighbourhood of the rectum in cases where there is stricture, or malignant disease, causing obstruction of this part of the intestine. They begin like the common abscesses of the rectum by ulceration of the gut, the difference being chiefly this, that in common abscesses the primary ulceration always takes place just above the sphincter muscle, whereas in these cases it occurs immediately above the obstruction, wherever that is situated, and that is usually about three or four inches above the anus. These abscesses that are connected with obstructions of the rectum from stricture, or malignant disease of the rectum, are generally not formed singly, there being several in the same patient. At first, there is one ulcer and one abscess forms, that bursts externally; and then a fresh ulceration takes place, another abscess forms, and that bursts externally also. They come slowly down by the side of the rectum, and you may have half a dozen such abscesses, or more, all open and discharging matter at the same time. Some of the external orifices are close to the anus, some on the buttock a considerable distance off, and some of the abscesses that have begun to form by ulceration above the obstruction may burst again into the gut below it.

It is right I should notice these cases, in order that you may distinguish them from common fistula of the rectum; not because I have any thing to say about the treatment of them, for it is needless to lay open abscesses connected with such diseases of the rectum. What a length of gut you must have to lay open! what an extent of bleeding there would be from the large incision which would be required! and after all no purpose would be answered; for probably as fast as one sinus was opened a fresh one would be formed. The only treatment such a case requires is this—when an abscess forms and does not come to the surface, but is lying and burrowing under the skin, you may introduce a lancet just to give the matter a free discharge outwardly, and prevent it extending further.

On fatty, or steatomatous tumors.

There are different kinds of fatty tumors, but the most common is the following. The fat resembles ordinary fat, except that it is rather of a more delicate and of a looser texture, and of lighter colour. It is composed of lobules with very thin membranes between them; and externally there is a thin membranous bag in which the whole mass is contained. This bag has a very loose adhesion to the parts in which it is imbedded, but the adeps which it encloses adheres pretty firmly to it.

These tumors, for the most part, form under the integuments in some part where there is naturally adipose structure. You never find them where there is no adeps originally; as, for instance, in the serotum, the eyelids, or the internal organs. But wherever natural adipose structure exists there this unnatural morbid growth of adipose substance may take place. The tumor is very often not detected when it is of small size. In some instances it remains stationary, but for the most part being once formed it gradually increases in size. It generally begins the patient knows not why or wherefore; but it occasionally seems to originate in some slight injury of the parts in which it is formed. For example, a gentleman was straining to raise his arm as high as he could, and he felt a sort of snap in the shoulder, and soon after that a fatty tumor appeared over the deltoid muscle. A lady was making an effort with her arm; something snapped, as she thought, in a part of the shoulder; soon afterwards she consulted me, and I discovered a small adipose tumor.

The diagnosis of a fatty tumor under the skin is generally sufficiently simple. There is a peculiar sensation communicated by the tumor to the fingers which it is difficult to describe in words, but which, when once felt, you will readily recognise afterwards. Sometimes the tumor is elastic, so that you might almost be led to suspect that it contained fluid, but a little practice will, for the most part, enable him to distinguish better. The tumor is generally pretty well defined, it is not productive of pain, it is not at all tender, and gives the patient no inconvenience, except when it attains a large size, and then it is merely troublesome from its bulk. Sometimes, however, the tumor is not situated in the fat immediately under the skin, but is in some more deep-seated situation. This renders the diagnosis more difficult. I remember a lady who had a tumor at the posterior part of the shoulder, and there were various opinions respecting its nature. No one seemed to be quite positive on the subject. On performing the operation for its removal, the trapezius muscle was found lying over it, some fibres of which being divided, out started a fatty tumor. A lady had a tumor of the breast (I am now speaking of what happened when I was almost a student). She was the wife of a medical man, and she had the opinions of four or five of the leading surgeons of that day. One thought that it was fungus hæmatodes, another believed it to be something else, and another could not say what it was. At last it was decided to cut down on the tumor, and then it was found to be a great mass of fat. It was situated under the gland of the breast, which being of large size, concealed the tumor completely, and being, as it were,

lifted up by it, was made to appear a great deal larger than it was.

When a fatty tumor has a deep-seated origin, it will sometimes make its way out from under the muscle, a small portion presenting itself externally, while the rest remains concealed. You are led to think there is a very small tumor, but when you cut down upon it you find it to be a large one. This happened to me last week. A patient consulted me concerning a tumor below the axilla. It seemed to be a small fatty tumor, about the size of half an orange, but I could not get my fingers behind it. It was evident that I could not trace its origin, and when I cut down upon it I found an enormous tumor proceeding from the axilla. It extended far back apparently into the space between the scapula and the ribs. In fact it was impossible to dissect out the whole of it, and I was forced to tie a ligature in the middle, and cut off the greater part, leaving the rest.

As a fatty tumor increases in size the skin becomes dilated in proportion. When it is of large size a sort of thick fascia is formed over it—such a fascia as is situated over a large old hydrocele or hernia. In different parts of the fascia there are circular spaces, into which the finger will sink as if it were into the substance of the tumor. The skin over a fatty tumor very rarely inflames and ulcerates. One might suppose that the pressure of the tumor would produce this effect, but it is not so. I have, however, known inflammation to take place in the substance of the tumor, and an abscess to form in its centre. A very remarkable example of this occurred to me in this hospital. An elderly man was brought in with an enormous fatty tumor on the back weighing many pounds. It had existed a number of years, and hung like a wallet behind. A year or two before he came in inflammation had taken place in the tumor, and an abscess had formed and burst externally. The abscess never healed, but continued to discharge profusely both matter and a sort of oil floating in it. It is worth while for me to mention what happened afterwards in this case. I dissected off the tumor, which was easily done, for it had not a very broad origin, and it was a very slight operation. The wound healed very readily, but when it was nearly closed the patient became very ill. I forget the exact symptoms, but I know that we had none of us any doubt that they arose from the sudden cessation of the profuse discharge of matter and grease from the interior of the tumor. These symptoms, however, subsided, and the patient recovered.

We know of no internal medicine, nor of any local application, that will disperse these tumors, and the only thing to be done is to

remove them by the knife. This may be done when the tumor is quite small. I do not, however, generally recommend the operation at this period, first, because the tumor may never increase, and as long as it is small it is of no consequence; and secondly, because the operation is really more easy when the tumor has attained a certain size. Still, it is better not to let the tumor go to any *very* large size; and for this reason, lest the pressure of the skin should cause it to contract adhesions to the neighbouring parts. Where such adhesions have taken place, the operation is rendered difficult, and you cannot be certain that you do not leave some small portion of it, which may be the nucleus of a future growth. As soon, then, as the tumor becomes large enough to be troublesome from its bulk, then you may dissect it out, and this is a simple operation if you know how to do it, and very difficult otherwise. Make a free incision of the skin, not upon the tumor, but into it, cutting fairly into its substance. Do not spare the incision through the skin, but let it extend from one end to the other. Then lay aside your knife, and you will find that with the fingers you can easily separate the cyst that contains the adipose matter from the neighbouring textures, pulling out one lobe after another till at last the tumor remains attached only at one corner, that is at the point at which the vessels run in and out. You have no bleeding in any other part of the operation, but in this last part of it you will generally find one or two arteries which you must secure by ligature. When the tumor is situated under a muscle, the operation is to be performed in the same way, with this exception—that besides laying open the skin, you must freely divide the muscle, cutting across the fibres.

There is another kind of fatty tumor which occurs not very unfrequently, but which, so far as I know, is not described in books. It is a deposit of fat, the tumor not being well defined, and there being no distinct boundary to it, so that you cannot say where the natural adipose structure ends, and where the morbid growth begins. I will mention to you one of several cases which I have seen, and which will explain sufficiently what I know of the matter. A man came to this hospital some 17 or 18 years ago, with a very odd appearance—an enormous double chin hanging nearly down to the sternum, and an immense swelling at the back part of the neck—two great tumors as big as oranges sticking out, one behind each ear. The patient stated that these tumors had begun to form three or four years before, and had been gradually increasing in size. They gave him no pain, but they made him miserable: and in fact had ruined him. The poor fellow was a gentleman's servant, and having such a strange grotesque appearance nobody

would hire him. I gave him half a drachm of liquor potassæ three times a day, and gradually increased the dose to a drachm. This was taken in small beer. About a month after he began to take it the tumors were sensibly diminished in size. He went on taking the alkali a considerable time, and the tumors continued decreasing. It was just then that iodine began to have a sort of reputation, much beyond what it deserved, for the cure of morbid growths, and I gave him the tincture of iodine. It was curious that while he took the tincture of iodine he lost flesh generally, but the tumors began to grow again. Finding this to be the case I left off the iodine, and gave the liquor potassæ a second time. He took an immense quantity altogether, and left the hospital very much improved, being directed to continue to take the medicine for some time longer off and on. I had lost sight of him for some time; when I happened to be requested to visit a patient in Mortimer Street. I did not observe the servant that opened the door, but as I came down he stopped me in the hall, and said that he wished to thank me for what I had done for him. To my surprise it was this very man. He had gone on taking the caustic alkali for a considerable time, and you may suppose how much he was improved by his being able to get a situation as a footman. There were some remains still of the tumors, but nothing that any one would have observed. I have seen some other cases of the same kind, and where I have had the opportunity of giving liquor potassæ it seemed to be of great service. But I have not tried it in every case, and I have been informed that in some other cases it has been tried to a great extent without the same good result.

These tumors feel like fat, but there is no distinct boundary, and they are not so soft and elastic as common fatty tumors. This deposit of fat may take place in any part of the body, but I have seen it more frequently in the neck than elsewhere.

There is another kind of fatty tumor, which, also, so far as I know, is not described by writers. A patient comes to you having tumors in different parts of the body as if there were absorbent glands under the skin. You will find several in the arm, several in the trunk, and perhaps a great number of them altogether. They generally give no pain, they grow to a certain point, and these do not get larger, but others form somewhere else. They occur in persons apparently healthy in other respects, and are not connected, so far as I have seen, with any other disease. I used to doubt very much what was the nature of these tumors, till at last there being one rather larger than usual in a patient who had several of them, I dissected it out, and it proved to be a fatty tumor;

but the fat was of more solid consistence than that belonging to the ordinary fatty tumors, which causes them to give a different feeling to the fingers. They are equally well-defined on the margin. Any one of these tumors that grows to an unusual size may be dissected out without any harm, but there being a great number of them, it would be absurd to think of dissecting them all out. Can anything be done in the way of medicine? I have given these patients the liquor potassæ in large doses, and certainly in two or three cases with very great benefit. The tumors in one case nearly or quite disappeared under this remedy. I suppose that in those, as well as in the other cases of which I have just spoken, the liquor potassæ acts in this manner: the greasy part of the tumor combines with the alkali, is taken into the circulation, and is thus carried off. It was upon this hypothesis at any rate that I was led to give this alkali. Whether it be, or be not, the right explanation, I will not say, but of this I am certain, that the remedy is often a very efficient one. But may the liquor potassæ be taken with safety in such large doses? Indeed it may, if you dilute it sufficiently. You cannot take even half a drachm in two ounces of liquid without its being inconvenient to the stomach, but you may take a drachm and a half in a large quantity of liquid two or three times daily without any harm. The best liquid in which to take liquor potassæ on this and in many other occasions, is fresh small beer. It seems to me to act better in small beer than when it is given in other ways, and the beer does not disagree with the stomach, because the alkali combines with and neutralizes the vinegar which it contains. It is the latter that disagrees with weak stomachs. The alkali and the vinegar together make a diuretic salt, and I suspect that this is advantageous; besides that the alkali is less ungrateful to the taste when taken in small beer than in any other way. However, there are some persons who really cannot take small beer, even with the alkali; and others, with whom small beer generally disagrees, can hardly be persuaded that an alkali alters its quality. If there be any reason for not giving it in beer, it may be given in milk and water, or clove tea, or ginger tea; but then it should be exhibited in smaller doses, because none of the alkali will be neutralised as it is by the acid of the beer. To do real good the alkali must be taken in large doses, and for a long time together—not for weeks, but for months. A patient may take it on and off for a great length of time without any mischievous effects.

There is a very remarkable kind of fatty tumor that sometimes occurs, though it is a very rare disease indeed. It is of rather firmer consistency than an ordinary fatty

tumor, and perhaps there are two or three or more in different parts of the body. When you cut down on it, you find that it is composed of pretty solid fat, and that it is covered with a reflected membrane just as perfect as the peritoneum or the pleura, or any of the reflected membranes of original formation. There is one layer of membrane covering the tumor itself, and then another which forms a loose bag round it; and there is a space between the two membranes filled with a halitus, so that they do not adhere. These tumors are troublesome to remove, because you must remove not merely the tumor itself, but the reflected membrane. How you are to distinguish these cases from other tumors I cannot tell: you can only make out the nature of the case when you have cut down on the tumor.

There is a tumor that occurs in the female breast, which Sir Astley Cooper has called the chronic mammary tumor. It is not a very good name, but no other has been given to it. This tumor is of a peculiar structure, in general lobulated; and when you examine one lobule, you find it is made up of smaller lobules, adhering to each other by loose cellular texture. What is the peculiar appearance which it presents under the microscope I do not know, but by the naked eye it is easily distinguished from malignant and other tumors of the breast. It occurs for the most part in young women, and there is reason to believe that sometimes it disappears spontaneously. I was called to see a young lady some years ago, who had a tumor on one side of the breast; and I thought that the disease was of this description. I recommended her, as it was of some size, to have it removed by an operation. I cut down upon the tumor, and dissected it out, or rather extracted it, which was done very easily in the way which I will mention presently. At the time of the operation it seemed to be not exactly the common chronic mammary tumor, though very like it; but when I examined it afterwards, I found it chiefly composed of fatty substance, but lobulated like a chronic mammary tumor. The wound healed, and there was never any return of the disease. This called my attention to the subject, and since then I have seen other cases, that satisfied me that this chronic mammary tumor has some actual relationship to the fatty tumor, the structure being probably modified by the particular organization of the part in which it is imbedded.

In the case which I have just mentioned, the character of the fatty tumor predominated; but from the structure of other tumors, it appears as if the two diseases run into one another; and even where the characters of the two tumors are most distinctly marked, there is this point of resemblance

between them—the adhesion of them to the neighbouring parts is just of the same kind, and they must be removed in the same manner, namely, by dividing the skin, and turning them out with the fingers, there being generally only one point of the tumor at which there is much adhesion, and that is, where the vessels pass in and out. Then I met with this case, which affords a further proof of the relationship between these two classes of tumors. There was a lady who had an enormous tumor of the breast. I could not say that it felt different from the natural breast, but it seemed as if the breast were grown to a monstrous size. I called in Sir Astley Cooper, it being a doubtful case, and the patient being a person of considerable consequence; and he agreed with me in thinking that it was more like hypertrophy of the breast than anything else (for there is such a disease as hypertrophy, that is, an increase of the natural structure of the breast, without any actual change of structure.) There was no hurry about it, and we tried pressure and some other remedies without any benefit. The tumor, however, continued to grow, the patient became tired of carrying about the load, and we recommended her to have the breast removed. Sir Astley Cooper was with me at the operation, and we set about it, believing that I should remove the whole breast. But when I came to cut down upon it, I found that the breast itself lay perfectly sound in front, while the tumor lay at the posterior part, between the breast and the pectoral muscle. I dissected out one portion of the tumor, and it had just the appearance of a chronic mammary tumor. Then, as I went on, I came to a mass of fat, which I drew out in the same manner; and then I came to another mass of chronic mammary tumor, but the whole connected together. The entire mass weighed probably two or three pounds. The breast itself was left perfectly sound. When we examined the tumor, we found it made up of both structures: at one part there was common fatty tumor, and at another chronic mammary tumor, the one being blended with the other, so that they could not be separated. The patient died perfectly well.

I have said that the skin over a fatty tumor does not readily ulcerate, but that matter may form in the tumor, and then that the skin may become ulcerated secondarily. But Sir Astley Cooper used to say, that he had no doubt a fatty tumor would sometimes alter its structure, take on malignant action, and become a malignant tumor. Whether he had any dissections to prove that, I do not know; but I have no doubt that he had seen instances in the living person which sufficiently justified the opinion; and I think the case I am about to mention

proves that he was correct. A farmer from the country came to me with what appeared a fatty tumor on the back. It was as big as your two fists put together, and it had existed for a great length of time. There seemed to be no doubt that it was a fatty tumor, yet it was a little more firm in consistence than fatty tumors usually are. I dissected out the greater part of the tumor; and on examining it afterwards, I found that it was composed of a fatty substance rather more condensed than usual, but that here and there throughout its substance there was a morbid growth, apparently belonging to the class of medullary or fungoid disease. It is reasonable to suppose, that if the tumor had been allowed to remain, it would have ulcerated and run the course of other malignant tumors.

I have thought it worth while to bring this subject of adipose tumors before you, because I think a good many of the facts which I have mentioned, though of course known to practical surgeons, are not to be found in books, and that it will be useful for you to be taught them, and not to be left to find them out altogether for yourselves.

MEDICAL REFORM.

To the Editor of the Medical Gazette.

SIR,

A PERIOD of calm has succeeded the storm which has been so long raging with regard to "medical reform," and whether I am justified in making any endeavour to revive the commotion is a point which I leave to your judgment.

Now, sir, I must avow myself in politics a Conservative: I have no desire to behold that utter subversion of those institutions which were founded by the wisdom of our ancestors, and to overturn which is the desire of men guided by the marsh-lights of self and faction; but, inasmuch as no human institute is or can be perfect, and as the state of society undergoes a gradual change which requires it, so I am willing to concede the necessity of an occasional and gradual modification of existing laws. The great point of agitation aimed at appears to be the re-arrangement of the whole genus—the manufacturing of new classes of practitioners, and abolishing old ones. Various have been the plans proposed. According to some, the "Hall" is to be quashed; that is, to be confined to making and dispensing drugs; the Colleges of Physicians and Surgeons are to be amalgamated—to become somehow chemically combined and decomposed into different grades, and many other plans equally pretty in theory, and equally impracticable and unnecessary: for, with all becoming deference to many celebrated ad-

vocates for reform, it appears to me that the existing grades of physician, surgeon, and general practitioner, are such as are required by, and which, indeed, have sprung from, the existing state of society. And what, let me ask, is the use of making new ranks if the individuals who compose them are not advanced? and here it is that I wish to advocate reform. Let me confine my observations to the student. Is it not a humiliating fact that men should waste their time and talents for two or more years, and then in six, or even three months, be worked up by a "grinder" to pass the examination of the Royal College of Surgeons? The fact need not be dwelt upon: it is one of the "great facts" of the time. And are such persons as these fit to be entrusted with the lives of Her Majesty's subjects? True it most certainly is that a very great number of those who go up for their diploma are in an eminent degree deserving of it; but the very fact of these "grinders" passing, reflects a disgrace on the College which ought speedily to be removed; and it surely must appear to every candidate, who has laboured to acquire a thorough knowledge of his profession, to be very little, if at all honourable, to pass that examination.

What, then, is the remedy? How can the death-blow be given to the office of "grinder," that is, to the "professional grinder?" The plan is simple,—is not new,—is easily put into operation, and has the sanction of the most learned bodies. At our Universities of Cambridge and Oxford, each college has an examination annually for men of the same year. Why, then, should this not be at our medical schools? Each student should, I think, be required to pass three of these annual examinations, which should be conducted by printed papers. That of the first year should embrace the subjects of chemistry, materia medica, and anatomy simply descriptive. In the second, anatomy, physiology, surgery, and medicine. In the third, midwifery, and a general examination on all subjects. They would, of course, be compulsory, and failure in one would throw the student back twelve months. Then, of course, prizes should be given to the student who is most proficient in each subject; and I should imagine that at many of our schools a fund might be established for a scholarship to the best general proficient. If such a reform as this could be effected, the student would take a much higher standing than he at present does, and the whole profession would, in a like degree, be advanced to a higher degree of dignity. The University of London has set the example of what examinations ought to be, and it is not a very gratifying circumstance to think that members of the College should be twice rejected at the M.B. examination. Let the

College follow this example. Let the examinations for the diploma, instead of taking place every Friday evening, take place every three months. The income of the College may possibly be slightly diminished by this mode of action, but a lustre will be reflected on that body by the members it will send out, which will raise it from its present twilight dignity into the clear and ever-beaming light of honour and renown.

I am, sir,

Your obedient servant,

D. H.

January 16, 1844.

HOSPITAL VISITS.

To the Editor of the Medical Gazette.

SIR,

MIGHT I be permitted, through the medium of the *MEDICAL GAZETTE*, to ask some of the medical officers of the metropolitan hospitals why the physicians and surgeons go round their respective wards at the same hour of the day, thus limiting the students to see either the medical or surgical practice, instead of affording them every opportunity of witnessing both, which, of course, would be the case if the physicians would attend the hospital at one hour, and the surgeons at another? I consider it especially hard, in cases where young men, like myself, have entered, and paid their fees as "perpetual students" to both practices; because if they attend regularly the three years' surgical practice required by the College of Surgeons, they are debarred from seeing, comparatively, any medical practice.

Hoping I have not taken too great a liberty in thus troubling you,—I am, sir,

Your most obedient, humble servant,

A MEDICAL STUDENT.

January 20, 1844.

[The Hospital visits are not literally made by all the officers at the same time, but we must say there is too much cause for the complaint made above, and we should be glad to see it removed.—*Ed. Gaz.*]

NEURALGIA OF THE URETER.

A GENTLEMAN, æt. 31, of a dark complexion and bilious temperament, somewhat emaciated, and with a countenance expressive of habitual suffering, came to me in the year 1839, complaining of the following symptoms: about four months before, he was attacked suddenly, for the first time, with acute pain, shooting from the direction of the kidney towards the corresponding testicle; the pain frequently extended down the inner part of the left thigh, and was so

excruciating as on one or two occasions almost to produce swooning, and generally brought on tendency to vomiting, sometimes violent retching. The principal seat of the pain was in the region of the kidney and along the course of the ureter. These attacks, at first occurring only once or twice a week, had latterly increased very much in frequency; the period they occupied varied from a few minutes to several hours.

This gentleman had always very active habits, and was much addicted to field sports. Many members of his family had suffered from gout. He never recollected having any lateritious deposit from his urine, nor had he ever passed small calculi. He had formerly drank hard, and had been much addicted to venery. He twice had clap; the last time, six or seven years before, was a very bad one; he never had stricture. He had lumbago, from exposure to cold, two years ago, which was cured by friction with turpentine.

He had no tenderness on pressure in the renal region, no pain in making water, which was emitted in a full stream, no tenderness, enlargement, nor deformity of the prostate. His appetite good, bowels regular, pulse natural.

His urine was of an amber yellow colour, depositing, upon cooling, a light cloud of epithelium, specific gravity 1019, acid in its reaction, not albuminous.

What should be the diagnosis in this case? It was not nephritis: the pains commonly attributed by authors to this disease really belong, as M. Rayer has shewn, to inflammation of the calyces, infundibula, and ureters. The extreme severity of the pain, together with the absence of albumen or pus in the urine, forbids its being attributed to the latter inflammation. From nephritic colic it differed in its long continuance, the absence of blood in the urine, the absence of calculi, and the pulse remaining undepressed, unremitting, and regular, during the attacks. The absence of pain during abduction and extension of the leg, forbade the idea of its being psoas rheumatism. The only conclusion to which I could arrive, after the most careful consideration of the symptoms, was that it was neuralgia of the ureter, probably involving the continuation of this duct in the substance of the kidney.

This gentleman had been cupped repeatedly, and treated alternately by acids and alkalies, before I saw him: I ordered him, in accordance with my diagnosis, large doses of carbonate of iron. I am unwilling to ascribe the rapid improvement which immediately followed to the influence of this medicine, having so frequently seen it fail in removing other neuralgic affections, but certain it is, the paroxysms very shortly ceased, and during a period of four or five

months that I afterwards occasionally met him, he assured me that he was completely cured, and his improved appearance corresponded with this statement.

Since that time I have met, in dispensary practice, with three or four cases similar to the foregoing, but less violent in their symptoms; and I am led to think that neuralgia of the ureter is a less rare disease than what is generally supposed.—*Dublin Journal of Medical Science.*

ACQUISITIONS TO NATURAL HISTORY.

THE *Allier*, corvette, after remaining four years in the archipelagos of the Pacific Ocean, returned to Brest in October last. She repeatedly visited New Zealand, the Marquesas, Otaheite, &c.; in short, all those places where so many treasures still remain to be explored for natural history.

M. Raoul, the navy surgeon, whose talent is only equalled by his zeal, has brought back fifteen chests from this long voyage; and their opening, at the Museum of the Naval Hospital, attracted a crowd of learned and curious spectators. The extensive herbarium, which has been preserved with singular care, is described in a *catalogue raisonné*, with drawings, which give a perfect image of nature, and preserve those characteristics which are always lost in part by drying.

His collections of birds and shells are equally valuable. The labours of this diligent *confère* will enrich our cabinet, and clear up more than one obscure point in science.—*Gazette Médicale de Montpellier.*

ON THE BEST METHOD OF REMOVING THE STAIN PRODUCED BY CHEMICAL MARKING-INK FROM LINEN TEXTURES.

BY BOETTGER.

NITRO-MURIATIC acid has been recommended for this purpose; but, without entering into the obvious demerits of this agent, which is neither fitted for general use, nor suited for cambric or fine linen, I propose a *concentrated solution of Liebig's cyanide of potassium, as a sure and harmless means of removing the stain of marking-ink from linen textures.*

In the preparation of this salt, it is essential that the ferrocyanide be as free as possible from sulphate of potash, to prevent the generation of a combination with sulphur during the process of heating, which would entirely defeat the object.

Names and marks on linen or wearing apparel, of *many years' standing*, may be

totally and effectually removed from the finest cambric, even without the slightest injury to its texture, by rubbing the mark gently with a rather concentrated solution of this cyanide of potassium. If a stain of common writing ink have been used in addition, in marking the linen, a hot concentrated solution of oxalate of potash must be afterwards applied. The red and black stains produced on the skin by the solutions of the salts of silver and gold may be perfectly removed by a solution of the above mentioned salt. It is necessary, however, to observe, that the skin should be intact, as this salt produces ill effects, if applied to open sores.—*Annalen der Chemie und Pharmacie*; and *Pharmaceutical Journal.*

LOCAL APPLICATION OF CALOMEL IN OPHTHALMO-PLENNORRHEA.

BY DR. LANER, OF BERLIN.

DR. LANER is able to verify, according to what has already been announced by some practitioners, especially by Dupuytren, Fricke, and M. Mayor (of Losanne), that this remedy produces excellent effects in the second stage of all the inflammations of the conjunctiva, by favouring resolution, but that it is especially productive of advantageous results, in cases of scrofulous inflammation, by hastening the progress of the resolution, and by removing, as by enchantment, the distressing symptom of photophobia.

He is also able to acknowledge the justice of the interesting observation made by Fricke, that calomel, applied to a healthy or diseased eye, determines only a disagreeable but transient sensation, whilst it irritates and inflames the conjunctiva to such an extent as to give rise to chemosis, and that in a very short space of time, when put in contact with the eye of a patient who is using a preparation of iodine internally.

It appears, from an observation of Fricke, that an iodide of mercury is in this case formed.

Drs. Kluge and Knippa have for some time, commenced employing this remedy, and its success has been at once so rapid and so decided, that no other treatment is resorted to in the obstetrical establishment of charity, at Berlin. The author exclusively employs it in all cases of ophthalmoplenorrhœa, and Dr. Liebold has assured him that in his *clinique obstetricale*, at Göttingen, its success has been no less decided than at Berlin.

The following is the mode of applying this treatment:—

A small hair pencil is impregnated with the finest possible powder of calomel; and, while an assistant raises the superior eye-lid, and lowers the inferior, the pencil is gently

struck, so that the powder which escapes from it may fall on the surface of the eye. This operation may be repeated a second time, if, in the first, a sufficient quantity of calomel have not arrived on the surface of the conjunctiva.

The contact of this powder causes an irritation so slight that, immediately after the application, the patient can open the eye.

In the ophthalmoplenorrhœa of newborn children, it should be resorted to on the appearance of the first symptoms of disease. One application *per diem* is sufficient; but, if the symptoms acquire great intensity, and if the disease appears to make rapid progress, two applications should be made in the twenty-four hours. In this case, it is indispensable to wash the eye frequently, in order to free it from the abundant secretion; at the same time, it is advisable to favour alvine evacuations, by the internal administration of calomel.

In general, by means of this treatment, cure is obtained in from four to ten days.—*Chemist.*

FRENCH ELECTIONS.

At the late concours for the Chair of Natural Philosophy, M. Gavarret and M. Maisial obtained an equal number of votes. M. Pouillet, the President, having then declared his vote to have been in favour of M. Gavarret, that gentleman was duly elected Professor of Natural Philosophy.

The other candidates were M. M. Guérard, Person, and Baudrimont.

The following presentation-list for replacing M. Edwards at the Academy of Moral and Political Sciences has been communicated.

In the first line, M. Peisse.

In the second line, *ex æquo*, M. M. Bucher, Dubois (of Amiens) Gurnier, and Lelut.—*Gazette Médicale de Paris*, Jan. 5, 1844.

THE BRODIE MEDAL.

A VERY handsome bronze medal has just been executed, having on one side a most excellent likeness of Sir Benjamin Brodie, while on the reverse is a female figure feeding the lamp of science. Beside the former appears merely the word BRODIE; the latter has round the circumference the following sentence:—*E tenebris tantis tam clarum ectollere lumen qui potuisti*; and beneath—*CONSOCHI ET DISCIPULI GRATULANTES.* MDCCCXLI.

AN ESSAY

ON

THE MEDICAL TREATMENT OF
PERMANENT STRICTURE OF THE
URETHRA,

*Read before the Physical Society, Guy's
Hospital.*

BY JOHN F. FRANCE,

Assistant Surgeon to the Eye Infirmary of Guy's
Hospital.

THE following observations were written in the hope of drawing into more general notice the utility of a careful therapeutic course and dietetic regulations in cases of permanent stricture, and of illustrating the principles on which such a system is beneficial; for although, by some scientific surgeons, such resources are not overlooked, yet it is to be feared that, by the great majority of the profession, they are disregarded, or, indeed, their efficacy denied, except when other local or constitutional disease coexists; and even in the more approved works on this complaint, mechanical dilatation, and the various ways of effecting it, are the predominant, if not exclusive, themes of discourse under the head of treatment.

Before the days of Sir A. Cooper it would seem to have been a frequent, if not invariable practice, in some places at least, to salivate stricture patients, under the impression that their disease was syphilis. Thus Benjamin Bell, a surgeon of great industry, and apparently of much experience, lays down the following rule: "Whatever," says he, "may, in disorders of this kind, be the immediate cause of obstruction to the free passage of the urine, a venereal taint is in general to be considered as the original cause of the whole: we have therefore desired that, at the same time the use of bougies is persisted in, the patient ought to be put upon a *very complete course of*

mercury, in order to destroy every possibility of his suffering again from the same cause; for we need scarcely observe that, so long as any venereal infection continues to prevail, little or no permanent advantage can be expected, either from the use of bougies or from any other remedy;" and, if I mistake not, the prevalence of these principles was borne witness to, and combated, by Sir Astley: hence, in fairness, we are compelled to acknowledge that, in the hands of men who thought and acted as Benjamin Bell seems to have done, this class of patients were little likely to suffer from *want of physic*. Can it be, that we owe to such erroneous practice our subsequent indifference to the auxiliary powers of medicine in this complaint, even as in other cases misguided zeal so often gives place to apathy?

General neglect of therapeutic resources certainly *prima facie* implies their experienced inefficacy; but this conclusion (believing it to be a mistaken one) I shall, in the following pages, oppose; and in doing so it is necessary to inquire from what class of medicines, independently of those which combined disease may indicate, assistance can be expected in the cure of stricture.

There is a tendency, in many diseases, to pursue a certain defined course, and then subside: it is most evident in the exanthems, in fevers, and the phlegmasiæ; and equally true, though masked perhaps by circumstances, in inflammatory local complaints. Thus, a phlegmon, having reached its point of greatest activity, will terminate, as the case may be, in resolution or abscess, and the normal condition of the part will usually then be gradually reestablished: so a peritonitis, an erysipelas, an iritis, are as really disposed to decline, and allow the natural action to be resumed, after having reached a certain point, as before that period they are prone to increase in violence. It is true, indeed, that according to the severity and activity of the inflammation, according

to the patient's powers, the vital importance of the part inflamed, or the delicacy of its structure, either life or the utility of the organ may, in the course or issue, be threatened or sacrificed; still, though the effects may be permanent, the disease itself tends absolutely to cease.

But should it so fall out, that the part affected is one continually exposed to circumstances calculated to originate, renew, or maintain the disease, then the disposition to subsidence, though not annihilated, is cancelled, and its accomplishment indefinitely deferred: hence arises the obduracy of some forms of conjunctival disease, and of amaurosis in artisans depending on their occupations for their livelihood; the intractability of inflammation of the synovial membrane, if the motions of the joint be not suspended, and the inveteracy of fissured ulcers about the anus. Now, although the effusion into the submucous cellular tissue of the urethra, which constitutes in most cases a permanent stricture, is not, indeed, like the foregoing examples, an original disease, but, in the majority of instances, a consequence of antecedent inflammation (as Key, Hodgkin, and others, agree), still, if analogy hold, as it is reasonable to presume it does, between this and other local plastic effusions into the cellular membrane, like them, if unimpeded, its reabsorption would spontaneously advance.

[In this particular appears a difference between the habit of ordinary serous membranes and that of the cellular: the former are more inclined to organize adhesive matter once poured out, and render it permanent, as is continually manifested in the peritoneum, pleura, pericardium, and aqueous capsule of the eye; the latter, to remove it again into the mass of the circulating fluids, as instanced in the eventual disappearance of the indurations around abscesses, wounds, tumors; the flattening down and disappearance of interstitial tubercles in parenchymatous iritis, &c.]

The preceding remarks are sufficient to establish the importance of removing whatever obstacles may exist to the full exertion of this salutary action of the absorbent vessels in cases of permanent stricture, an indication which (if not altogether chimerical) demands equal obedience with that directing us to stimulate those vessels, as by the pressure of instruments we are wont to do.

What obstacles, then, are there? To what peculiar influences is the urethra obnoxious? The double function of the canal at once suggests itself as palpably the operative drawback upon the *vis medicatrix*.

That the high state of excitement, vascular and nervous, into which the urethra is thrown during coitus, must greatly contribute to aggravate morbid action, is so obvious and unquestionable, that I shall

content myself with simply pointing out the fact, and adding, that he who would most successfully combat stricture of the urethra must authoritatively interdict sexual indulgence to his patient.

But the function of the urethra as a urinary organ cannot be thus summarily dealt with, nor its exercise be suspended at pleasure: here is a duty which, injurious or not, must be performed several times a day: hence repose, so needful to every part of the body when the seat of disease, is here unattainable. Much, however, depends upon our understanding this fact properly, and not remaining content with the bare statement, in general terms, that the function of the urethra will not permit a state of quiescence. Indeed, such an expression is true in a very modified sense only, the canal itself being absolutely passive during micturition, except when the last few drops of urine are expelled; for, anteriorly to the bulbous portion, there is no muscular apparatus; and posteriorly to the same, the action of its muscles produces contraction of the calibre, and so would rather impede than facilitate the transit of the urine: and this view is confirmed by our finding, after death, muscular hypertrophy of the bladder, and not of the urethra, in connection with stricture.

Such being the case, the process of micturition, as it affects stricture, may be reduced into three parts, to one or more of which we must attribute whatever influence the function of the urethra exerts in protracting its diseases. These are,—the muscular effort,—the passive opening or distension of the canal,—and the application of urine to its surface.

1. It is difficult to conceive that the urethra sustains any detriment, or hindrance to recovery, from its expansion in micturition, if, as I have endeavoured to substantiate, it be indeed passive during that process. In the majority of permanent strictures (previously, at least, to operative interference) there is no ulceration, and the continuity of the mucous membrane is perfect. Were it otherwise, an analogy would be established between strictured urethra and fissured anus: every time an evacuation should be attempted, the ulcerated, but perhaps healing, surfaces must needs be torn open afresh; and we can readily understand how decidedly this would oppose return to a state of health. But, on the contrary, while the urethra is free from ulceration, far from having grounds to believe that its mere dilatation in micturition is injurious, we know that similar dilatation, if gently effected by art, is one of the most efficacious means of cure. We must seek, therefore, in the impelling muscular effort, or in the reiterated application of urine to the diseased

part, for that circumstance in the function of the urethra really inimical to its restoration.

2. Now muscular effort in micturition being only exercised upon and by the bladder, its effect upon the stricture can be indirect alone. Patients suffering from these obstructions are compelled, in order to evacuate the bladder, not only to allow contraction of the muscular coat of that viscus, but to call into auxiliary action powerful voluntary muscles—all those, in short, which, forming the parietes of the abdomen, are capable of compressing the contents of that cavity. But in doing so, not the viscera of the abdomen alone, but the blood-vessels also, sustain their share of pressure; and the venous plexus immediately under the prostate gland and bladder (from which, as well as from the penis and urethra, its radicles spring), and over the levator ani, cannot escape severe and direct compression by the strong action of that muscle antagonized from above: and when we reflect that, in bad cases, the violent congestion thus caused is renewed very many times a day, and on each occasion is continued for some minutes, we cannot but admit its highly injurious influence on the disease.

It is only in this indirect manner that the muscular effort of micturition can prejudicially affect the strictured portion of the canal: with the changes produced by it behind the seat of stricture I have at present nothing to do.

3. The influence exerted by the flowing urine upon the channel it traverses must bear relation to the properties of the former and the susceptibility of the latter: thus, when the urethra is healthy, we find highly concentrated urine will irritate it, as often exemplified in spasmodic stricture supervening after excess at table; if, again, the urethra be inflamed, healthy urine will produce the same result as in gonorrhœa.

I cannot think that either augmented irritability of the canal in sympathy with disorder of the stomach and general constitution (to which some attention has been bestowed), or the varying powers of stimulation possessed by the urine in disease (which has been much less regarded), has received that extended and particular consideration, which the importance of each in the study and care of these cases demands. A quotation or two, however, will suffice to show that even the latter point has not been altogether overlooked. Thus Brodie, perhaps our highest authority upon diseases of the urinary organs, teaches, that the injurious effects of acidulous beverages, and of blisters, upon stricture, arise from their imparting additional acrimony to the urine; and he states, in the commencement of his work, that "whatever increases the stimulating qualities of the

urine, so as to make it a cause of irritation to the parts with which it comes in contact, may lay the foundation of spasmodic stricture, and this, whether the excess of saline ingredients be of acid or alkaline reaction." The same author subsequently speaks of "the liability to spasm in permanent strictures being sometimes increased by a too abundant secretion of lithic acid by the kidneys;" and adds his evidence, how highly conducive to the success of the local treatment the correction of this state of the secretion proves: to use again his own forcible words, it will "enable you to accomplish by means of the bougie what you would in vain have attempted to accomplish otherwise." He, however, limits the utility of medicine to those cases in which such disorder of the urine exists.

Mr. Stafford, who wrote a useful monograph on stricture, with the view of recommending the lancetted stilette, alludes to cases of stricture depending on extreme irritability of the canal, or over stimulating urine, and refers to the latter becoming so in consequence of indigestion.

These quotations vindicate the truth of the position taken above, viz. that a very important influence is exercised upon the urethra by the fluid applied to its surface; I am, however, concerned to prove more than this, viz. that the influence in question most commonly tends to protract disease, and that, although the urine may be in a perfectly healthy state*. This belief was first impressed on my own mind by some cases which fell under my care several years ago, when dresser at this hospital, and has been confirmed by subsequent thought and experience. I will first briefly narrate the principal points in these cases, premising that they are by no means singular; rather do they form examples of what commonly occurs under the same circumstances; as many observant surgeons who have practised the operation here used, or those which in principle are allied to it, can bear witness.

William Wrenn, æt. 49, was admitted into hospital, March 7, 1838, with permanent stricture. The disease had followed a blow on the perineum from falling astraddle on a chair six years before; since which, difficulty of micturition had gradually increased, and about three years before his admission had given rise to retention and extravasation of urine. After recovering from these dangers, he still laboured under chronic cystitis; his urine was ammoniacal, loaded with mucus, and sometimes he was forced to

* There may appear an inconsistency in urging this point after having stated that the cellular tissue beneath the surface is the seat of stricture, but it must be borne in mind, that while submucous effusion is the source of obstruction, chronic inflammation in the lining membrane and its diverticula is the cause of that effusion.

evacuate it every five minutes. When received into hospital he was found to have, in addition to the symptoms just named, a stricture utterly impermeable to catheter or bougie, while the urine passed away, not by the contracted urethra alone, but also by several fistulous openings in the perineum and scrotum, and even above the pubis. During his residence in hospital he had another attack of extravasation of urine, treated in the ordinary way, by free incisions into the infiltrated tissues, &c; and a severe diarrhoea, which then supervened, caused the further treatment of the stricture to be for the time postponed. A consultation was now held, and the long duration, impermeability, and obstinacy of the stricture, having been considered, the propriety of opening the urethra behind it was decided upon. For six weeks after the operation, the urine having a free outlet by the wound in the perineum, the stricture was not interfered with, but left in entire repose, neither urine nor surgical instrument being applied to it. At this period, however, examination being made, it was discovered that the urethra had spontaneously recovered itself to such a degree that a No. 5 catheter could with little difficulty be passed through the whole canal. From this time the cure progressed uninterruptedly to completion; chronic cystitis subsided, the fistulae closed, the urine was passed exclusively by the urethra, and might be retained for several hours without inconvenience.

The foregoing it will be allowed is a striking proof of the existence of that self-restorative power in the urethra, on which I dwell at first; only needing, it would hence appear, suspension of the function of the canal, (or in other words relief from contact of urine, and from congestion arising as above explained), ere it exert itself with equal energy and effect. The same result we are warranted in believing would more quickly be achieved, in less inveterate cases, under the same circumstances; for it will not escape notice that in this instance the disease was of the most intractable kind—of traumatic origin, many years' duration, and to a degree amounting nearly to a perfect closure of the canal. The following case is closely parallel to the preceding.

John Kelly, a sailor, æt. 49, was admitted March 28, 1838, with permanent stricture, the commencement of which he ascribed to a blow on the perineum ten years before, followed immediately by hæmorrhage from the urethra and abiding difficulty of micturition. He was much neglected, much exposed to vicissitudes, and underwent a great variety of treatment, in this country and America, with varying success; the stricture having been more than once temporarily cured, but returning again with equal or in-

creased severity. At first catheters and bougies relieved him; then they failed, and recourse was had to the lancetted stilette, with which the contracted portion of the canal was pierced. He derived the greatest benefit from this operation, followed up by the introduction of bougies; but the effect was transient: on return to his duties the complaint recurred; and when he was admitted a remarkably callous stricture was found extending from an inch or two anterior to the bulb, nearly to the apex of the prostate gland; the firm indurated effusion being easily perceptible in the perineum. The urine was extremely ammoniacal, and deposited brownish mucus of alkaline reaction: each attempt at micturition was made with much pain and straining, and so frequently as to preclude rest by night or day. It was found impossible to penetrate the stricture by ordinary sounds; the caustic bougie was therefore employed, but without making material progress, while it augmented the irritability of the canal, and produced paroxysms of intermittent, with still greater deterioration of appetite, strength, and rest. After patient continuance with these, in conjunction with various palliative medicinal means, for some weeks, an abscess formed in the perineum, and was lanced. A few days afterwards it was determined to cut into the membranous portion of the urethra. The course of the urine was thus diverted, the patient was greatly relieved, and less than five weeks interval elapsed before a successful attempt was made to introduce a No. 4 catheter. The disease from that period yielded steadily and satisfactorily to the ordinary treatment by dilatation.

This case, like the former, develops the existence of an inherent disposition to recovery in the strictured urethra, the conditions necessary for its successful operation seeming to be, freedom from the venous congestion induced by straining at micturition, and simultaneous cessation of the action of the urine on the lining membrane.

Is it, then, too much to infer from these facts, that the urine derives from its saline constituents an irritating property highly conducive to the maintenance of disease in the urethra?

This opinion, first suggested to my own mind by the cases just related, has many strong grounds of support. I will cite in its favour another case or two. In the Guy's Reports, about a year ago, was given the history of a man, who had a stricture so firm and impenetrable, that in the endeavour to pass it, a false passage was inadvertently made into the bladder, and this not being discovered, was exclusively employed for some time. Meanwhile, the stricture, thus left to itself, became to a certain degree relaxed, and one day to the surgeon's surprise

readily admitting an instrument, informed him of the existence of a false passage, at the same time that it apprised him of the recovery of the true. Brodie tells of a gentleman who had suffered from stricture of the orifice of the urethra from childhood: this part was ulcerated, inflamed, and tender, and so continued despite treatment, until the extremity of the canal was laid open freely, and thus relieved from irritation. The same surgeon gives his testimony to a fact which bears weightily upon the present question, when he says, "rigor seldom follows the use of the bougie immediately; it almost always occurs after the patient has voided his urine, and seems to arise, not as the immediate effect of the operation, but in consequence of the urine flowing through the part which the bougie has dilated;" and Sir Benjamin goes on to say, that the protection of the surface of the urethra from the contact of the urine by the use of a gum elastic catheter, has, with him, invariably succeeded in preventing this unpleasant symptom. In like manner, Guthrie gives a case, in which the urine passing over the stricture, after the use of an instrument, always caused spasm and fever, or retention, and in which the continued use of the gum catheter gave entire relief. The same author remarks upon the facility with which strictures are cured, after puncture of the bladder has emancipated the urethra from its office; a fact well known to most practical surgeons as true of the sister operations likewise.

From all this it is pretty clear, that the urethra, when the subject of stricture, undergoes an amount of irritation from the highly stimulating properties of the urine, sufficient in some individuals to excite most violent and obvious effects; but not the less certainly impeding the cure, when these severe symptoms are not manifested; inasmuch as liberation of the membrane from contact of the urine (whether by operation or gum catheter), is constantly followed by a rapid improvement the most decided. And in perfect harmony with this view are the phenomena produced by irregularities in regimen or diet, when we find a patient with permanent stricture, and habitual difficulty of micturition, experiencing total inability to evacuate the bladder after a feast or debauch, when the urine is more than ordinarily loaded with saline matters; or after sexual intercourse, when the canal, already morbidly susceptible of the natural stimulus of the urine, is rendered so in a still higher degree.

There are, then, two elements in the act of forced micturition, which have a direct influence in keeping alive diseased action in the strictured urethra; one being the application of an acrimonious fluid to its surface; the other, venous congestion of the mucous membrane and the circumjacent tissues. Now there is but one method in which both

can be completely avoided; viz. by resorting to operative measures, with the aim of diverting the course of the urine, as exemplified in the cases first detailed: in this way, all effort in evacuating the bladder is rendered needless, while the urethra, like a maniac in seclusion, is set free from the reiterated irritation it was before subjected to, and left undisturbed, to resume in tranquillity a healthier condition.

This plan, however, it were almost superfluous to remark, is applicable in a comparatively small number of cases only, viz. 1st, when retention of urine produced by absolutely insuperable stricture calls aloud for immediate and decided remedy; 2dly, in cases of long-standing impenetrable strictures, which have resisted patient and well-directed attempts to introduce instruments, and create much suffering after these endeavours. Oftentimes these cases are accompanied by ammoniacal urine loaded with mucus; and they threaten, by their long continuance, by the agony they cause, by disturbance of the natural actions of the whole urinary system, as well as of the patient's sleep, appetite, and spirits, to impair the organic integrity of the bladder, ureters, and kidneys, and irretrievably to undermine his constitution. In such cases (and they are far from infrequent), if not already too far advanced, I unhesitatingly advocate the operation above alluded to, as the more lenient measure, relieving the patient from much greater and more protracted pain and danger than it inflicts.

But while few cases, comparatively, require this extreme course, yet the same principle, on which it effects the cure of stricture, is applicable in the treatment of the disease generally. By this mean, indeed, we at once place the urethra in repose; but by others, we may prevent it being violently congested, or strongly irritated, and thus place it in a condition, approximating at least, to the former. Towards the attainment of this end we have an important source of assistance (in addition to tonic and alterative medicines, which, by improving the constitution of the patient, dispose all parts of his body to more kindly action, and anodynes which soothe and tranquilize his system generally), in the power of divesting the urine in great measure of its acrimonious qualities; so lessening its energy both as a local irritant, and as an exciter of spasm. Regulating the food and regimen of the patient—restricting him to the observance of a plain and simple (nourishing it may be, but) unstimulating dietary—providing that the secretions of the liver and skin shall be carried on with proper activity, and separate their due share of the debris of the body from the system, nor throw (as is too often done by their failure) more than its proportionate duty in this behalf on the kidney;—all will greatly con-

tribute to this immediate aim, and much, very much, may be done by care in these respects. Highly essential, too, is it that the bowels should be kept free,—not purged. Abernethy (to whom we are so much indebted for directing attention to the intestinal canal and its appended viscera, and) on whose recommendation many suppose they employ active purging in various complaints, is said to have altogether disclaimed experience of its effects; his desire was to keep the bowels gently open, not to produce diarrhoea. If, in stricture, we purge, we keep up irritation in parts closely adjacent to, and strongly sympathising with, the diseased urethra; we induce those contractions of the abdominal muscles, and consequently that congestion in the tributaries of the internal iliac veins, which we are most anxious to avoid. But if, on the other hand, we simply unload the intestinal canal, particularly the colon and rectum, of all fecal accumulation, and keep them free, we at once relieve those veins from mechanical pressure, and promote the secretions. If the case be a sufficiently severe one, the recumbent posture, and local depletion by leeches, are likewise commendable, as facilitating the relief of the urethra from a state of hyperæmia.

But, besides reducing the urine to a healthy condition, whether by attending to the stomach and its ingesta, or to the secretions of the skin, liver, and intestinal canal, we may exert a power over stricture by influencing the properties of this fluid still further, viz., 1st, by medication; 2dly, by dilution.

It may be matter of question, whether, as the chemical reaction of the urine when most healthy is acid, it would be rendered less stimulating to the parts with which it comes in contact by such administration of alkaline medicines as should render it neutral. I have already quoted the authority of Brodie in evidence that urine of actually alkaline reaction is unnaturally irritating to the urethra, but this point might easily be stopped short of. Be this, however, as it may, at least acidity in excess, or alkalinity of the excretion, imperatively demand the exhibition of the appropriate medicines to alter these conditions respectively.

Bearing in mind the beneficially soothing effects of copaiba both in gonorrhœa and hemorrhoidal affections, I believe that if fairly tested in the complaint now under notice, it would prove highly serviceable. Nor should the surgeon overlook the salutary results of the moderate use of gin in stricture cases, but avail himself of them. I assume its efficacy as unquestionable, since it is established by the concurrent testimony of most patients; and they are, commonly, no heedless observers of the phenomena of their own disease. Its usefulness may be ascribed either to its impart-

ing some medicinal virtues to the urine, or to its augmenting the secretion of the kidney; and this brings me to speak, secondly, of dilution of the urine as a remedial means.

2dly, Dilution of the urine manifestly, if a remedy at all for permanent stricture, is one which must be resorted to with great caution, and careful watching of its effects; since it would, *primò facie*, seem indefensible to cause a man, who has already the utmost difficulty in passing his urine, to secrete double or treble his usual quantity. Yet there are very sound reasons for asserting that this plan is not only justifiable and scientific in principle, but in practice good. If there be truth in the position,—that to the acrimonious quality of the urine is, in a great degree, attributable the prolonged existence and intractability of permanent stricture, (since the irritation induced thereby at the part diseased is both directly injurious by maintaining morbid action, and indirectly by giving occasion to spasms at the seat of stricture, then straining to overcome the obstruction and expel the urine, and then congestion of the urethra in consequence),—if this argument be valid, then to dilute the secretion must be to expedite the cure. Of course the utmost circumspection should be exercised in the choice of the means we employ to act upon the kidney, as well as vigilance in marking the results of the change upon the individual patient; and previously to resorting to the milder diuretics, and the free use of mucilaginous beverages and slops, we must not forget those essential items of treatment before enjoined, viz. regulation of the functions of other organs, and maintenance of the general health. The measure, if thus judiciously had recourse to, holds out reasonable hope of making less continually necessary the use of the sound and bougie, and reducing these instruments from the nearly exclusive estimation in which they are at present held, to be regarded as but portions (however important ones) of an extended system.

In addition to what has already been advanced in favour of this plan, some further evidence remains to be adduced in its support. Thus, I may mention the popular belief in the efficacy of gin, to which allusion has been made. The report, whenever a patient has made trial of it in moderation, invariably is, that it has facilitated the urinary flow; and I give full credence to such statements as to facts easily explicable: for gin, taken by patients with this intention as a medicine, and not for the purpose of intoxication, is probably in quantity insufficient to disorder the actions of the stomach, or the kidney; it does but augment the secretion of the latter, and affords us an unequivocal example of increased urinary secretion, occurring simultaneously with relief of the disease. Again, to turn to routine practice in a complaint presenting,

in some features, analogy with that under discussion, who will deny the excellent effects of the diuretic treatment of acute gonorrhœa? Yet in this case, as in stricture, the nature of the malady is such, that every act of micturition is contemplated by the patient with dread, and as tolerable only because inevitable. Nevertheless, we systematically exhibit diuretics, while we strictly enjoin frequent and copious draughts of diluent fluids; and we pursue this course no less habitually than successfully.

Various objections may be urged in opposition to similar treatment of permanent stricture: among the first would be—that more duty would be thrown on a part which it is desirable to keep as much as possible at rest. In reply to this, it is to be observed, that quiescence of the urethra being (as before contended) identical with its freedom from irritation and congestion—though truly the canal may be more frequently used if diuresis be promoted—yet it is, at the same time, protected against these causes of injury,—the urine acting no longer directly as a source of irritation, nor indirectly as a cause of congestion. If, again, it be said,—that suffering must be augmented, an act productive of pain being more frequently repeated,—it should not be forgotten that precisely the same argument may be applied to the treatment of gonorrhœa on similar principles; but fortunately we have in the latter disease such proof of the fallacy of this reasoning as may well lead us to more than suspect its unsoundness in stricture.

In conclusion, briefly to recapitulate the plan of medical treatment recommended in concert with, and in support of, necessary mechanical appliances. It consists in the exhibition of—

1st, Those remedies which, by promoting the general health, and allaying excitability of system, diminish the irritability of the urethra.

2dly, Those which, by removing pressure on the pelvic viscera, obviate congestion of the same organ.

3dly, Those which, assisting the healthy functions of the chylipoietic viscera espe-

cially, prevent the elimination of an undue quantity of saline matters by the kidneys. And,

4thly, Those which, by augmenting the amount of fluid, lessen the proportion of saline constituents, and consequently the irritant property of the urine.

It is needless to particularise the means of fulfilling the above indications; let but the general principles be recognised, be borne in mind, and be closely followed out in practice, according to the exigencies of individual cases, and they will be found auxiliary in no small degree to the success of the mechanical implements, with which, it were too much to hope, we shall ever, in this disease, be able completely to dispense.

Cadogan Place, Belgrave Square,
January, 1844.

ON THE STATISTICS OF FEVER IN ST. THOMAS'S HOSPITAL;

WITH REFERENCE TO TREATMENT.

By H. BURTON, M.D.

(For the London Medical Gazette.)

[Continued from page 510.]

Age on the duration of fever.—1stly, in recoveries. 2dly, in fatal cases.

THE results enumerated on Table VI. lead to the conclusion that young persons at and under 20 years of age are more susceptible of fever, but less prone to die under its agency, than others at an advanced age; and so far as my experience serves, the greater immunity of youth, as regards fatal fevers, is also observed, but in a limited degree, in respect of the protracted forms of the disease in recoveries, and the young appear to regain their health sooner than the more aged, according to the results enumerated on the following table.

TABLE XII.

70 cases of Spotted Fever.	21 cases between 4 and 15, average 12 years.	42 cases between 16 and 45, average 25 years.	7 cases between 46 and 53, average 48 years.	Difference between results in cases aged	
				12 and 25 years.	25 and 48 years.
Average day of fever on admission	8	11	11	3	0
Average day of return to a meat diet after admission. }	13	15	17	2	2
Average duration of the fever in days from its commencement.	21	26	28	5	2

But although it is consistent with a pathological knowledge of the organic lesions which occur in advanced life, to find the period of convalescence in fever is protracted by age, yet the influence of age on its duration in recoveries is limited and subordinate to that of the day of fever, among patients of the two first periods of life represented on the above table, under 45 years of age; for

if cases are selected which were admitted on the same average day of the fever, their duration will be seen to vary in a very trifling degree, and to be rather in favour of advanced life; but after 45, and under 64 years of age, this agent assumes a preponderating influence, as far as may be inferred from the results in a limited number of cases, over the day of fever. Thus:

TABLE XIII.

40 Cases.	16 cases between the ages of 4 and 15 years.	16 cases between the ages of 16 and 45 years.	8 cases between the ages of 46 and 64 years.	Differences between	
				15 and 45 years.	45 and 64 years.
Average day of fever on admission . . .	$8\frac{1}{8}$	$8\frac{1}{8}$	$8\frac{3}{8}$	0	$\frac{2}{8}$
Average day of return to a meat diet . . .	$14\frac{1}{8}$	$13\frac{3}{4}$	16	$\frac{3}{8}$	$2\frac{1}{4}$
Average duration in days of the fever } from its commencement . . . }	$22\frac{1}{4}$	$21\frac{7}{8}$	$24\frac{3}{8}$	$\frac{3}{8}$	$2\frac{1}{2}$

In recording, therefore, statistical data relative to the duration of continued fever and the age of the patient, it is desirable to state also at what period of the fever he was admitted, with the view of correcting the result of treatment for these two modifying agents.

2dly. Age on the duration of fatal cases.

The influence of age, which has been

shewn to be limited over the duration of fever in recoveries, is still less obvious over that of fatal fevers, and when viewed in relation to the nature of the organic lesion it appears to be of very secondary importance.

This conclusion is partly confirmed by the results of 198 fatal fevers enumerated in the following table.

Among the 24 patients who died at St. Thomas's there were 8 between the ages of 46 and 70 years, whose average

age was 55 years; they were admitted on the 10th day of their fevers, and died on the 18th day, or at the same period of the disease as the total number of 24 patients admitted on the corresponding day at the age of 35 years: hence, among my patients, a difference

of 20 years of age, *ceteris paribus*, made no obvious alteration in the length of time the patients survived. Again, 19 patients, aged 23 years, who had fever complicated with cerebral disease, according to Dr. S. Smith, lived only 18½ days; whereas 52 patients, also

aged 23 years, but who had fever with abdominal lesions, lived, under the superintendence of M. Louis, 26 days; and it may be observed, also, on Table XIV., that the minimum duration of the series of fevers termed cerebral was shorter than the maximum duration of the series of fevers complicated with abdominal disease, by as many as 18 days.

On the supposition that fevers complicated with severe cerebral and thoracic disease prove more speedily fatal than other varieties with abdominal disease, and that, *ceteris paribus*, each variety terminates at a period respectively pathognomonic, I was led to compare the periods of their fevers at which my patients either died or recovered.

But the impossibility of comparing cases of fever precisely similar, some of

which terminate in health and others in death, forbids any definite conclusion being drawn from the results of the comparison.

It is, however, remarkable that the average duration of the 24 fatal cases enumerated in Table XIV., was almost precisely equal to that of 229 cases which terminated in recovery, after deducting four days for the interval between the cessation of the fever and the period of return to a meat diet, as representing the therapeutic in contradistinction to the pathognomonic duration of the fever.

But this accordance is not so manifest when a comparison is instituted between the duration respectively of the fatal cases and recoveries for the corresponding weeks, as exhibited in the following arrangement:—

TABLE XV.

St. Thomas's Hospital.		Cases.	Average duration in days.	Differences between therapeutic duration of fever in recoveries, and in fatal cases.	Differences between pathognomonic duration of fever in recoveries, and in fatal cases, after deducting four days from therapeutic duration.
Periods of fever on Admission.	Terminations.				
First week	Recoveries .	110	20·2	7·2	3·2
	Deaths . .	9	13·		
Second week	Recoveries .	119	24·8	4·8	0·8
	Deaths . .	9	20·		
All periods	Recoveries .	229	22·6	4·6	0·6
	Deaths . .	24	18·0		

The near accordance of the terminations of the two series of fatal fevers and recoveries admitted respectively in the second week, and at all periods of the disease, leads to the inference that many more of the fevers enumerated among the 110 recoveries, and which were admitted in the first week of fever, were complicated with abdominal lesions than could be ascertained by the symptoms observed during life, and by the existence of which their convalescence was protracted beyond the duration of the nine fatal cases which were characterised chiefly by cerebral and thoracic symptoms previous to death. And it would be an interesting point, with reference to the pathology of fever, and also useful in relation to prognosis, to determine whether fevers, strictly cerebral from their commencement, of an adynamic character, do not invariably terminate either in death

or recovery during the second week of their course.

Duration in reference to the epidemic prevalence of fever.—In evidence of the milder character of the fevers admitted on the decline of the epidemic, and on its supposed cessation, it will be seen on the following table that convalescence was established in 29 of the 144 fevers during the first week after their admission; whereas during the epidemic fever no patients returned to a meat diet during the first, and only 34 in the second week of their respective fevers; in fact, all the numbers represented in the last column under the head of “differences,” afford similar proofs: it will be seen, also, that an amelioration began to take place during the first part of 1838; and the first column of “differences” between the returns of 1837 and 1838 will give a comparative notion of its amount.

TABLE XVI.

Periods from the commencement of fever at which 251 patients returned to a meat diet.	Number of Weekly Returns.					Weekly Differences for Six Years.
	1837.	1838.	Weekly Differences for Two Years.	Total in 1837 and 1838 to June 24th.	Total, after June 1838, of Subsequent Years.	
First week . .	None	None	None	None	29	29
Second week . .	12	22	10	34	81	47
Third week . .	27	29	2	56	27	29

Annual totals .	52	55	3	107	144	37

But although the average duration of the epidemic fever in 1837, after admission into hospital, is shown to have been more protracted than it was after June 1838, when fever was much less prevalent, yet the annual average mortality, with one exception, on Table I. among my patients was less. Hence the duration of fever which terminates in recovery, and the mortality from it of the same years, do not increase in the same ratio: and their difference points out the necessity of taking the epidemic constitution of the atmosphere into calculation when estimating the effects of treatment in recoveries from fever as well as in fatal cases.

It is probable the epidemic constitution of the air not only determines the virulence with which the febrile poison acts on the blood, but also the direction to particular organs on which its chief power is exerted. But the variable lesions which have been developed in connection with fatal fevers, at post-mortem examinations, during different epidemics, and by the nature of which their duration has been shewn to be modified, are not so unequivocally detected during life by symptoms, and consequently, in the cases which recover, it is often impossible to pronounce an opinion, with any justifiable confidence, as to the precise nature of the organic lesion in them, by which their duration was respectively modified, although all were treated under conditions apparently similar: hence it is to be feared that no numerical calculation will afford much useful information to the practical physician in single cases. Nevertheless, in a series of many cases the results of treatment under similar conditions are so remarkably uniform that a knowledge of them will probably assist in making

a correct prognosis as regards the duration of fever, and also serve to check any hasty conclusion in favour or condemnation of particular plans of treatment.

To the difficulty of discriminating between the several varieties of adynamic fever, which bear a near resemblance to one another, many of the discrepancies as to their duration in recoveries may be perhaps ascribed; but when similar, or nearly similar cases, are compared, all will, I think, be found to continue nearly the same average period, to the commencement of convalescence. In this expectation an attempt has been made to exhibit, on the following table, the results observed in 229 fevers which terminated in recovery under my superintendence at different periods during the last six years, in relation to the modifying causes which have been already separately noticed in this communication; and I believe the data which furnished them have been accurately calculated.—See next page.

The influence of the four quarterly seasons on the duration of fevers which recovered is not obvious on the above table, irrespective of the epidemic constitution of the atmosphere; but it will be observed that the fevers of the years 1837 and 1838, when epidemic, were, with two exceptions, more protracted from their commencement than those of the subsequent years, and in one instance by as many as three days among the males, and in the other their duration was nearly equal. Again, among the female patients the only exception occurred in the second week of the fourth quarter, when, according to my notes, the fevers admitted in the second weeks of the years subsequent to the epidemic were characterised by

great prostration and unequivocal symptoms of pulmonary and abdominal disease.

It is hardly requisite, after the remarks which have been made, to enter upon any further explanation of the individual results enumerated in the above comprehensive synopsis; but as they are numerous, and the relations existing between them intimate, I will venture to impose an additional tax on the reader's patience for the purpose of directing his attention to a few which appear to be least manifest. In the first place he will have the goodness to observe that the influence of sex for corresponding periods over its duration from the commencement appears likewise to have been controlled by a more powerful agency, and although in some instances the females recovered a few days earlier, yet in others their recovery was more protracted than that of the males; and for the whole period the average therapeutic duration of fever in the two sexes respectively differed only 2-10ths of a day, among 229 patients, from its commencement; but the fevers in the females admitted in the first weeks were more protracted by one day than those in the males for the corresponding weeks. No influence can be traced to age within the average periods of life enumerated on the table.

Some opinion may be formed of the relative severity of the fevers admitted at different periods by comparing the number of cases in each week with the weeks in which the fever terminated in the two sexes respectively, and the comparison will shew that a large majority of patients returned to a meat

diet in the third and fourth weeks from the commencement of their fevers.

The fevers admitted in the first weeks of their course, and which terminated during the first week after admission, were very few, and also mild; whilst those admitted in the second week, and which also terminated in the first week after their admission, were, for the most part, nearly convalescent, and not seriously complicated, whereas those fevers which were protracted over the fourth week from their commencement were severe, and complicated with either abdominal or thoracic lesions. The remaining majority I consider were, for the most part, characterized by cerebral symptoms, and by a uniformity as to the periods at which they terminated.

There is no obvious reason for doubting the probability of this uniformity being invariable in similar varieties of fever; and it may perhaps be received by pathologists as corroborative evidence of the nature of the particular kind of fever which prevails at different periods in various localities. This opinion has been rendered probable by the uniform average duration of fatal fevers, and is strengthened by a comparison of the results observed in 14 cases of recovery at St. Thomas's, with 14 analogous cases which are very minutely described by Mr. J. H. Browne, in the valuable Reports of Guy's Hospital for April 1843, pp. 331, &c. and which were admitted during corresponding months of the year, and days of fever nearly, into that institution. Thus—

TABLE XVIII.

Winter months.	Number of cases.	Average day of fever when admitted.	Average day of return to a meat diet after admission.	Therapeutic duration of fever from its commencement.	Time in Hospital.
St. Thomas's .	14	$12\frac{5}{4}$	15	$27\frac{5}{4}$	$32\frac{3}{7}$
Guy's Hospital	14	$12\frac{7}{2}$	$17\frac{6}{7}$	$29\frac{7}{2}$	$32\frac{3}{7}$

It appears probable, from an inspection of the results of treatment enumerated on the foregoing tables, with reference to the circumstances which have been shown to modify the duration of fever, that a series of cases, limited in number, will furnish as much useful information as regards prognosis in single cases as a more numerous

series. But it should be understood that the results contemplated were obtained by different kinds of treatment, and as they may have been modified by each, I propose, at a future period, to inquire into the comparative efficacy of the particular plans which were pursued.

CONTRIBUTIONS

TO

ANATOMY AND PHYSIOLOGY.

BY ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

[Continued from p. 578.]

*On the Corpus Luteum.**Opinions of scientific observers.*

1. *Bacr.*—The corpus luteum is formed by a thickening of the inner membrane of the ovarian vesicle (vesicle of De Graaf). It is not a new body, but merely the inner coat in a greater degree of development.

2. *Montgomery.*—The corpus luteum is formed between the coats of the ovarian vesicle (vesicle of De Graaf), its substance being pervaded by the small vessels passing from the inner to the outer coat.

3. *Lee.*—The corpus luteum is neither produced by a thickening of the inner layer of the ovarian vesicle (of De Graaf), nor is it a deposit of new substance between its tunics, but it is placed outside both tunics of the ovarian vesicle, and having the stroma of the ovary in immediate contact with it.

The dissection in our own case, recorded in the first part of these Contributions, induces us to think that it is the outer tunic of the Graafian vesicle, and particularly the inner surface of that tunic, which ultimately assumes the thickness and complicated appearance as seen on a section being made of the body.

Table of measurements in 17 cases (*to all appearance authentic*,) of the so-named corpus luteum, after impregnation, from the 5th to the 280th day.

1. Day after supposed impregnation had taken place.
2. Names of those who have recorded the case.
3. Longest axis of the bisected corpus luteum.
4. Shortest axis of ditto.
5. Thickness of the glandular structure.
6. Central cavity.

From this table it will be observed, that there exist great differences in respect to the size of the body at different periods of gestation. The largest recorded is that by Dr. Clark at the 62d day; the smallest by Dr. Lee at

1	2	3	4	5	6

the 62d day! This is puzzling, inasmuch as it occurs in cases selected for their undoubted authenticity, and the accurate and truly scientific manner in which the cases have been presented to the public: it is doubly so, when we reflect on the fact, already mentioned, that perhaps no two persons will agree in opinion with regard to a section of the human ovarium. Whether the person may have had children or not? whether the bodies displayed by the section are, or are not, the effect of impregnation?

That Sir E. Home was so fortunate as to record perhaps the earliest case after impregnation in the human subject, no one seems inclined to deny. The history of the case is given in detail, and every thing which can render it authentic and satisfactory to the scientific mind has been recorded by Sir Everard, in his great work on *Comparative Anatomy*.* He seems to us to have done the case the greatest justice, not only in the method of his dissection, but in the manner in which he has recorded its various stages. The drawing and engravings are beyond all praise.

In brief, no more satisfactory case has since been given to the public; a surprising fact, when we reflect how

* The reader will be pleased to observe that it is my brother alone who writes this. I do not partake of his opinions.

easy it is to follow in the wake of a great discoverer, and how extremely numerous the fry have been who have followed in the wake of Sir Everard Home! Were it not attended with great expense, the friends of Sir Everard should still publish the case, with the engraving, as a separate monograph, for we repeat that we ourselves have witnessed one of the most accurate anatomists mistake the plates referring to the virgin case, for those of the servant-maid's case, and thus embroil his ideas to such an extent as to induce him to look upon the description as a downright imposture.

We have said that Sir Everard Home, in his lectures, refers to the plates in so superficial a manner, and even in most cases erroneously, that we shall be at the pains to give them here in detail; a mode of examination which we strongly suspect many of the small fry who have followed have adopted, not with the view of elucidating truth, but of ascertaining to what extent they could pilfer and appropriate.

CASE.—“A servant-maid, æt. 21, on or about the 7th January, 1817, became pregnant, and died epileptic on the 15th; that is to say, 7 or 8 days after becoming pregnant. On dissection the uterus was found enlarged, and the whole, with its appendages, were put in alcohol for future careful examination. On the right ovary, and on the most prominent part of its external surface, is a small ragged orifice, a longitudinal incision made close to the orifice, when a canal was found leading to a cavity filled with coagulated blood, surrounded by a narrow yellow margin, in the structure of which the lines had a zig-zag appearance. Upon examining the cavity in this ovary, it had an oval form, it contained a coagulum of blood, and was surrounded by a yellow margin similar to that which surrounds the corpus luteum.”—Lecture on Generation, p. 289, 294.

The plates given by Sir Everard Home, illustrative of this case, are the following:—

Plate 102.—Uterus and its appendages.

Plate 103.—Right impregnated ovary; section of.

Plate 104.—Left unimpregnated ovary; section of.

Plate 105.—The ovum itself.

Plate 102.—*Uterus and its appendages.*

Nothing can exceed the beauty and perfection of this drawing and engraving; the dissection was judicious, and the only thing wanting was a little letter-press description; that added to the plate itself is worse than ridiculous. “The uterus laid open from behind, to shew the human ovum in the situation in which it was discovered.” The objects are not magnified, the ovum being scarcely a line in its greatest diameter, and so much resembling the surrounding structures, that no one, we are satisfied, will observe it without a direct reference. The minute body so imperfectly alluded to by Sir Everard in his Lectures, may, however, be observed with ease on the surface of the inner membrane of the uterus, about 1 inch 7 lines from the os uteri, the neck of the uterus being entirely plugged up by a mass of a peculiar albuminous substance (always present in all cases of impregnation), rendered more solid no doubt by immersion in alcohol. We are the more particular about this albuminous substance, inasmuch as we have seen it actually supposed to be the ovum alluded to by Sir Everard! The right ovary measures 1 inch 6 lines at its fixed margin, and 6 lines deep where the mammillary shaped projection is beautifully represented, indicative of the presence or recent escape of a fruitful ovum, and consequently the presence of a corpus luteum.

This plate gives a view of the uterus opened from behind; and the right ovary presents precisely the appearance indicating the presence of a *corpus luteum*; it has lost its compressed oval shape, having prominences towards its proximal pole.

Plate 103 gives a view of the section, evidently greatly magnified, though not stated to be so, of the right impregnated ovary: it measures 3 inches in length, with a breadth (each segment) of 1 inch 4 lines. There are no letters of reference, and the cut surface presents a very complex mottled appearance; numerous cysts have been cut across, and of course blood-vessels: near the proximal pole, and in the situation of the swelling indicating the situation of the corpus luteum in the entire ovary, as seen in plate 102, a large irregularly shaped body, represented as having been bisected; and on the left segment I observe a dark line indicating the canal alluded to by Sir Everard Home.

The central cavity in the meantime is indistinctly shewn, and the yellow circumference with its plicæ is really not represented at all. Near the distal pole of the ovary the knife has bisected a body presenting all the appearance of a corpus luteum at the third or fourth month of pregnancy.

That the ovary was an impregnated one, and had given off an ovum, I think the very drawing proves beyond a doubt. The case is about as authentic a one as could be wished for, and it is only to be regretted that a more carefully detailed description of the engraving of the section, as seen in plate 103, had not been given to the public. I have already remarked that the section presents the appearance of another corpus luteum.

The appearance of this second corpus luteum would at the present day be declared to be that of the corpus luteum at the full period of gestation, and indicating that the young woman had had a child previously; always taking it for granted that Sir Everard was correct in identifying the recently impregnated Graafian vesicle, and of which, we think, the engravings leave no doubt.

These are all the plates given by Sir Everard Home, as connected with this extremely interesting case, and they appear to us perfectly satisfactory. They prove nothing more, however, (but they completely prove *that*), than 1st. That an ovarian vesicle had been impregnated. 2d. That an ovum had left the ovary, and was found in the uterus on the 7th or 8th day after impregnation. 3d. That the ovarian vesicle after impregnation takes on a high degree of vascularity, gets greatly enlarged and distended, and ultimately gives rise to the appearance (*unfortunately called*) corpus luteum. 4th. That the minute body found in the uterus was the ovule there can be no reasonable ground for doubt, and that the dissection and description given of it are *good* for the period at which they were made. We repeat that little or nothing more has been done in human anatomy on this subject.

We now proceed to examine the other cases alluded to by Sir Everard Home in his Lectures; and this is by no means so agreeable a task. Our inquiry, however, leads directly to a most important question: viz., What were Mr. J.

Hunter's opinions on the subject of the human corpus luteum?

The plates given by Sir Everard Home illustrative of the corpus luteum in the human ovaria, which he admits were taken from J. Hunter's museum, are plates 108, 109, 110, 111.

Plate 108 is a view of a fœtus found in the ovary after the person's death, and although the drawing and engraving are exquisitely beautiful, yet the appearance of the ovary and corpus luteum are by no means satisfactory. We are said to point to "portions of the ruptured corpus luteum," but these look like nothing we have ever seen of that body.

Plate 109 gives three views of the human ovary externally, and their section: fig. 1 and 2, "view of the human ovary that did not contain the ovum from which the child was produced. It contained a corpus luteum *nearly the full size!*"

We remark on these figures, particularly the section fig. 2, that these are distinctly delineated true corpora lutea, one nearly obliterated, the other six lines in its longest diameter, with a distinct central cavity and altogether strictly resembling a fruitful corpus luteum towards the latter period of pregnancy, remaining from some unknown cause larger than usual, apparent and distinct. Thus we should have been inclined to have stated the very reverse of Sir Everard Home, viz. that the ovary was that from which the child had been produced, and we should have felt the more confirmed in this opinion from an examination of the other ovary (same plate, 109, fig. 3 and 4), whose section (fig. 4) presents the appearance of numerous Graafian vesicles cut across, condensed white irregular spots, supposed by Sir Everard to have been the fruitful corpus luteum! and one very small, but well-marked, considered by Sir Everard to be a new corpus luteum forming.

We can gather from the engravings and letterpress that these ovaria were from a case in the Hunterian collection of a woman who had died immediately after the child was born, consequently at the 9th month of pregnancy, and we feel satisfied that our views will be borne out by all practical men, viz. that fig. 1 and 2 mark the fruitful ovary, instead of 3 and 4, as supposed by Sir Everard: the preparations

it is admitted existed in the Hunterian museum, and in all probability the sections were made by J. Hunter himself. We are by no means certain, however, that the description of the figures is either correctly given, or is that of Mr. Hunter. It is evident that the section had been made after the immersion of the preparation in alcohol, and consequently may have been made by Sir Everard himself, in which case he has evidently mistaken the unfruitful for the fruitful ovary.

Fig. 5 and 6 (plate 109,) are external view and section of an ovary of a woman, aged 70, "*to shew how little of the appearance of corpora lutea remains.*"

We remark, that our wonder is that there should be any remains of corpora lutea at the age of 70. The appearances delineated certainly do look like the remains of corpora lutea; but Sir Everard has not, apparently, observed that the view is an enormously magnified one. The large hydatid alluded to by Sir Everard would in the present day be considered a Graafian vesicle, and altogether the history of the ovary would require undoubted authenticity as being that of a person aged 70.

Plate 110 contains five figures: 1 and 2 are either copies of Sir Everard Home's case of the "servant girl," already delineated in plates 102 and 103, or they are not. Now we do think, and indeed feel quite assured, that these figures are a repetition of the *right* impregnated ovary from the servant maid's case; but that case (and which we consider authentic, most interesting, and satisfactory, and altogether Sir Everard Home's own case) is stated by our author to be one at the seventh or eighth day after impregnation, whilst the figures in the plate, which we consider copies of each other, are stated to belong to a case at the fifth day. If they are not copies, but refer to preparations in Mr. J. Hunter's museum (we mean the museum left by Hunter at his death), then it is clear that Mr. J. Hunter had met with some very early case of impregnation in the human subject: and this impression leads us still more deeply to deplore the destruction of the manuscripts left by Mr. Hunter, and burned by Sir Everard Home. It even throws doubts on the case of the

servant maid, recorded by Sir Everard Home; for he may have applied the opinion of Hunter to the case of the servant maid. They are merely alluded to in the letter-press to the plates as the human ovary *five days* after impregnation.

Figs. 3 and 4 of plate 110 shew the human ovaria six weeks after impregnation; and fig. 5 is a transverse section of the same ovary.

We remark here that figs. 3 and 4 are most interesting figures, and go greatly to destroy the theory of Sir Everard himself. The view of the corpus luteum, which has been eight lines in its longest diameter, is most magnificent, satisfactory, and precisely such as we would have supposed to indicate a period of six weeks' gestation. It will be found, by referring to the table (page 605), that the measurements come as near as possible to those given by Røderer and Montgomery. The Graafian vesicles cut across are numerous, and we also observe some remains of former corpora lutea. If the details of this case had been given by Sir Everard, we feel assured that they would have been perfectly accordant with the present received opinions regarding the appearance of a fruitful impregnation at the sixth week. The corpus luteum, properly so called, is seen to be assuming a more distinct outline and a specific character.

Plate 111 gives views of three ovaria, and is a most interesting plate. Figs. 1 and 2 are views "of ovary and section in which no ovum was contained." There are, we observe, numerous Graafian vesicles, which have been cut across; and it also resembles so strongly the section of a virgin ovary in our own museum, and the details of which we have given at the commencement of this part of the contribution, that the drawings might pass for it. There are no appearances of corpora lutea; and we therefore perfectly agree with Sir Everard that no ovum had come from it.

Figs. 3 and 4 "are views of the external aspect and section" from which the ovum escaped; and fig. 5 is a view of the ovum itself.

These five figures, which we have gathered with no little difficulty, refer to one case which we now copy from Sir Everard Home's lectures, page 304.

"In a young woman, æt. 20, with a perfect hymen, one of the ovaria was found to contain a corpus luteum, in which was an ovum arrived at its full size; the second covering or chorion already formed, by means of which the ovum had a slight adhesion to the inner surface of the cavity of the corpus luteum; so that if this woman had lived, and this ovum had been impregnated, it would have proved an ovarian case." (Lecture on Generation, p. 304.)

We do this the more readily, that we are aware that the illustrative views of this case have been, by many accurate observers, mixed up with that of the servant-maid's case; and assertions made, and errors attributed to Sir Everard, which he has neither made nor committed. The fault lies, in our opinion, with his assistants, in referring to the plates.

We shall return to the case when considering the ovule, and shall confine our observations to the appearance which the ovary and section (figs. 3 and 4) present. The ovarium itself measures one inch, five lines, in length, and only six lines at its greatest depth, presenting no appearance of the presence of a corpus luteum. Its section, magnified two diameters, exhibits great vascularity, two or three Graafian vesicles bisected, and near the centre a well-defined and undoubted corpus luteum; this, however, must have been extremely small, being only four lines (if not magnified) in its longest axis. The ovum is represented *in situ*, as contained in the right segments; and fig. 5 gives a magnificent view of the body, we presume, removed from its bed. We refrain from further comment by merely remarking that the corpus luteum is about the best delineated one we have seen, and, recollecting its extreme minuteness (only four lines in its greatest diameter), would indicate some previous fruitful pregnancy, notwithstanding the appearance of a hymen, and the existence of the minute hour-glass-shaped body which Sir Everard removed from its interior.

Abstract.—It is ever to be lamented that the MS. papers of J. Hunter were destroyed. The inexplicable nature of the figure to which we have alluded in a former page, raises a suspicion in the mind that some early case of impregnation had occurred to Hunter, of which the drawings and notes merely

were left at the time of his lamented death. Whether the idea that corpora lutea are formed in the human virgin ovaria be Home's or Hunter's, we have found it impossible to make out; but the correct description given of the figure, and to which we have alluded, we feel inclined to consider altogether as a case of John Hunter's. It is admitted by Sir Everard that the preparation is in the Hunterian museum; and of course the leading or direct statement, that it was a corpus luteum at the sixth week, must have been made in some MS. catalogue. Were the corpus luteum the body "which secretes the ovule" preparatory to being capable even of impregnation, and which appears to have been Sir Everard Home's opinion, how is it that it increases so much in size after having not only performed its function in, as Sir Everard supposes, forming the ovule, but after that ovule has been impregnated, left the ovary, and sojourned in the uterus for a period of no less than six weeks? Sir Everard's virgin corpus luteum, as represented in the plates to his lectures, at plate III, figs. 3 and 4. The corpus luteum is only about three lines in its longest diameter, one and a half in its short diameter; and he designates this as having arrived at its full size!

Now the corpus luteum, when seen soon after impregnation, measures three or four times the size of the above—a fact, indeed, recorded by himself in the sixth week case!

John Hunter's inquiries into this very subject—that is, the formation and true nature of the corpus luteum—were most extended, but of course these inquiries were made directly only on the lower animals. The very term of corpus luteum or glandulosum, is applicable only to the structure as observed in the lower animals. That these bodies are found in all stages in sheep and oxen, whether virgin or not, whether impregnated or not, we are quite certain; but even when the so-named corpus luteum is found in the human ovarium, and a *foetus in utero* to guide us, the body bears little resemblance to the corpora lutea in the sheep, cow, pig, &c.

Confining our attention, therefore, solely to human structure, we are of opinion that the following queries require solution:—

1st. To what extent do the ovarian

vesicles (vesicles of Graaf) become developed in the human virgin?

2d. If developed beyond the mere elementary vesicle, so that the embryo may be demonstrated, will there be found any structure representing the yellow plicated tunic, at present considered the very test of impregnation?

3d. Does an ovum ever leave the human virgin ovarium?

Appendix.—Since the preceding remarks were arranged, the author has had an opportunity of examining the ovaria of a woman who had died on the fifth day after delivery at the full period of gestation. The patient died of puerperal fever. The ovaria, in this instance, presented a remarkably thin compressed appearance. The uterine tube, and its fimbriated extremity on the left side, appeared increased in size, and to have suffered from the inflammation in common with the uterus, the lymphatics of which contained pus. Upon a section being made of the ovarium—which was, upon the whole, of the usual size—a very distinct corpus luteum was found. We have given its dimensions in the table at page 605. Careful dissection of the characteristic portion of the body—that is, the yellow plicated structure—proved it, we think beyond a doubt, to be an organized texture resembling a gland. It was firm, and could have been readily turned out of its bed in the stroma of the ovarium. The central white line was very distinct, equalling a line and a half in length. The yellow plicated structure, there can be no doubt, is simply the outer layer of the Graafian vesicle.

Between the segments of this corpus luteum I observed a very distinct vesicle, which I examined with great care. It consisted of two tunics, and contained a thickish fluid. It will be seen opened up in the preparation.

I have opened up the uterine tube, and the longitudinal folds are well displayed. The structure, more especially towards the fimbriated extremity, seemed distinctly muscular.

The above memoir, as I have already said, was drawn up by my brother in defence of Sir E. Home, *as an observer*; had he known as much of the two cliques supporting Sir Everard, viz. that of the Royal Society, and that in the body of the College, as I did, he would, I believe, have declined the defence.

[To be continued.]

CONTRIBUTIONS TO PATHOLOGY.

By JOHN PERCY, M.D. Edin.

Physician to Queen's Hospital, and Professor of Organic Chemistry, Queen's College, Birmingham.

(For the London Medical Gazette.)

Analysis of Albuminous Liquids.

MAY the 15th, 1841, I received from my colleague, Mr. W. S. Cox, the liquid which he obtained by tapping a female labouring under ascites. I was present at the operation, which was performed at 6 p.m. May the 14th. The female was of middle age, and was probably affected with hepatic disease. I made two analyses. The liquid had a pale straw colour; and was slightly turbid, owing to suspended flocculent matter. Sp. gr. 1817·8. Temp. 64° Fah. It restored completely, yet slowly, the colour of reddened litmus paper. The evaporation was effected in the first analysis over the steam-bath, and in the second over sulphuric acid in vacuo.

1.	250 grains.
Water	238·0
Albumen	9·5
Indeterminate organic matter	0·8
Salts	1·9

250·3

Error in drying ·3 in excess. The saline matter consisted principally of chloride of sodium. It contained also alkaline sulphate and carbonate. Neither phosphoric acid nor lime were detected. Part of the excess arises from the carbonic acid in combination with the alkaline base being estimated.

2.	300 grains.
Water	285·00
Albumen	10·24
Organic matter soluble in spirit	0·5
Ditto insoluble in spirit, but soluble in water	1·6
Salts	2·36

299·70

Error of loss ·3. The residuum obtained by evaporation of 300 grains in vacuo for three days was 15·0 grs. That obtained by evaporation of 250 grains over steam-bath during three hours was 12·0, which would probably have suffered a little further reduction by a more prolonged evaporation. At 12h. 48m. the residuum weighed 12·1, and at 1h. 28m. when the operation was discontinued, 12·0. Accordingly, the difference of result between the two modes of evaporation, is a loss of 0·5 by evaporation over the steam-bath; for 300 : 15·0 :: 250 : 12·5.

In the first analysis we have 9·5 of albumen, and consequently we should from this have 11·4 in 300 grains of liquid. However, we have only 10·24. Difference 1·16.

This error is probably due to defect in washing. In the second analysis we have, on the contrary, an excess of indeterminate organic matter. If, from this excess (the whole amount being 2.1), we deduct the amount of deficiency in the albumen in the same analysis (1.16), we shall find that the error is clearly accounted for. The difference between the weights of saline matter in the two analyses is 0.08. For, $250 : 1.9 : 300 : 2.28 ; -2.36 - 2.28 = 0.08$.

Calculating from the first analysis, we have in 1000 grains—

Water	952.0
Albumen	38.0
Indeterminate organic matter	3.2
Salts	7.6
	<hr/>
	1000.8

Error of excess 0.8

I received from my friend, Dr. Wright, the liquid obtained by tapping a female affected with chronic peritonitis. The case has been published by Dr. Wright in the *Lancet*, Feb. 1842.

Characters of the liquid.—Colour reddish brown. Shortly after its evacuation, a considerable quantity of tremulous coagulum of a blood-red colour was spontaneously separated, after subsidence during the night. The coagulated matter (fibrin) contracted into a very small volume, and collected at the bottom of the vessel; while the supernatant liquor was transparent, and had the usual pale brown colour of serum. A portion of the liquid was filtered immediately after the operation, while yet warm, and coagulum was again formed in the filtered liquid. Sp. gr. 1020°. Temp. 62° Fah. I employed 750 grs. for analysis. The evaporation was conducted first in the ordinary steam-bath, and then in Berzelius' apparatus for drying at 212 Fah.

Analysis of 750 grains in the first column, and of 1000 in the second.

	1.	2.
Water	705.4	940.5
Albumen, with fibrin and red particles in minute quantity. }	34.2	45.6
Matter extracted by water and dissipated by heat, lactic acid?, trace of urea, &c. }	1.9	2.5
Saline matter, consisting of chlorine, sulphuric, and phosphoric and carbonic acids*; and of soda, lime, and magnesia }	7.2	9.6
Loss	1.3	
	<hr/>	
	750.0	

* Derived by destruction of organic compound containing soda.

In searching for urea I employed $1\frac{1}{2}$ pint, of the ascitic liquid. It was evaporated to dryness over the steam-bath. The residuum was well triturated in a mortar, and then treated with rectified spirit. The spirituous solution was removed by squeezing through calico, and was afterwards filtered through paper. This solution was carefully evaporated over the steam-bath. A small quantity of liquid, of syrupy consistence, and of a light brown colour, remained: it restored the colour of reddened litmus. To a portion of this residuum I added a very small quantity of distilled water, and then a few drops of nitric acid. Some flocculent white matter was not dissolved by the water. The nitric acid precipitated small white flocculi, in which a crystalline form could not be detected. By the addition, however, of the acid, the same peculiar odour was evolved as when the residuum of common urine is treated by nitric acid in the process of obtaining nitrate of urea. I next added common rectified aether (which always contains a large proportion of alcohol). I stirred well, decanted the aetheral solution, and left it to evaporate at a very low temperature. On cooling, I obtained a mass of crystals, which, by the aid of the microscope, were found to be modified rhomboidal plates.

Pure nitrate of urea was dissolved in a small quantity of water, containing nitric acid, and then treated with the same aether, in the manner described above. Well defined crystals of nitrate of urea were formed by evaporation.

I dissolved the crystals obtained from the ascitic liquid in a small quantity of distilled water, and then neutralized with pure carbonate of baryta. The whole was evaporated to dryness at a gentle heat over the sand-bath. The dried mass was treated with cold alcohol of 804°: the alcoholic solution was filtered, and left to evaporate spontaneously during the night. On examination the following morning, crystals were observed at the edge of the syrupy liquid which remained. I then carefully evaporated this liquid on the sand-bath; a quantity of white matter was left, which did not present at first any decided appearance of crystallization; but on careful examination I still observed some well-defined rhomboidal plates. After a short time, however, the white matter having been exposed to the air, and having, probably, absorbed moisture, presented a distinct frosted appearance, occasioned by delicate needles in parallel bundles, variously placed in regard to each other. I have been thus minute, because I was not able by the use of alcohol in the usual manner to satisfy myself of the presence of urea. The rhomboidal plates which were observed after the treatment by carbonate of baryta were probably nitrate of urea which had escaped the

action of the carbonate of baryta. There was present some organic matter which prevented the separation of the nitrate of urea in a distinct crystalline form by the simple addition of nitric acid. Oxalic acid occasioned a flocculent precipitate in the evaporated æthereal solution. Dr. Wright found urea in the saliva in this case.

Liquid of Ovarian Dropsy.

I was favoured by my colleague, Mr. Knowles, with the liquid which he evacuated by paracentesis in a case of ovarian dropsy, October 1811. Characters:—turbid; colour brown; viscous; froths by shaking like a solution of soap. Filters slowly and clear. Reaction alkaline, restoring completely, yet slowly, the colour of reddened litmus. Sp. gr. 1035·2. I operated upon 500 grains. The evaporation was effected first over the steam bath, and then in Berzelius's apparatus.

1000 grains contained	
Water	885·4
Albumen	94·0
Organic matter, with alkaline chloride, and some alkaline carbonate } Alkaline ash from incineration of } albumen }	18·0 2·6

1000·0

The dry residuum was washed, as usual, with boiling distilled water until the water ceased to be appreciably affected by nitrate of silver.

Liquid of Hydrocele.

Nov. 16th, 1811, I received from my friend, Mr. Mackay, the liquid of hydrocele, obtained by tapping from a youth of strumous habit. Characters:—It had a pale straw colour, and contained suspended innumerable small shining scales, of a pearly aspect. It had not a perceptible smell. The sp. gr. of the filtered liquid was 1024·5; temp. 57° Fah. It restored the colour of reddened litmus.

I filtered 1509 grains of liquid, and washed with cold distilled water what remained on the filter. By thus washing, I removed some serous liquid, and a minute quantity of red particles, which tinged the shining matter on the filter red. The red particles gradually subsided in the water. There now remained on the filter a mass of beautiful, colourless, shining, scales, of which, after careful drying over the sand-bath, I procured 2·9 grs. These crystalline scales dissolved in boiling rectified spirit, and exactly resembled cholesteroline. The liquid, even after filtration and complete separation of the scales, deposited a minute quantity of flocculent matter and red particles, and became transparent.

I operated upon 500 grs. The drying was conducted first over the ordinary steam-bath, and then in Berzelius's apparatus.

1000 grains of the filtered liquid yielded	
Water	927·4
Albumen	59·2
Fatty matter dissolved by æther	Trace
Organic matter dissolved by alcohol	1·2
Ditto ditto water	2·2
Chloride of sodium, with trace of } chloride of potassium }	6·0
Soda and lime, with sulphuric, } phosphoric, and carbonic acids }	4·0

1000·0

Liquid of ascites containing only a trace of albumen.

Mary Jukes, æt. 43, became a patient of the Queen's Hospital, Feb. 1, 1843. Has had three children. Ill during the last nine years. Was tapped for ascites twelve months ago by Mr. Crompton, of this town, Ascites. Measures about 3 feet 3 inches in circumference at the umbilicus. Pain in right hypochondrium, shooting to the right shoulder. Frequent nausea, and occasional vomiting. Pyrosis. Appetite capricious. Never had jaundice. Catamenia reported regular. Urine scanty, not albuminous. Has not been accustomed to rise in the night to pass water. Tongue moist and coated. Bitter taste. Bowels generally confined. Prolapsus uteri. She still continues under my care. A great variety of medicines were prescribed, consisting principally of diuretics, tonics, and laxatives. But the circumference continued to remain nearly the same; sometimes slightly diminishing, at others slightly enlarging. At length, at the importunate request of the patient, I consented to the operation of paracentesis, which accordingly was performed by my respected colleague, Mr. Knowles, Dec. 16th, 1843. Fifteen and a half pints of clear liquid were evacuated. The patient has continued to be much relieved. The effusion probably depended on obstruction in the portal system.

Character of the liquid.—Colourless and limpid, like water. Sp. gr. 1007·2; slowly restored the colour of reddened litmus. No turbidity occasioned by boiling. Slight milkiness by nitric acid. Turbidity and precipitation of flocculent matter by tincture of galls in a much greater degree than by nitric acid. I operated upon 500 grains. The evaporation was effected first in Berzelius's apparatus, and then two days over sulphuric acid under a glass shade not exhausted.

Analysis of 1000 grains.

Water	987·60
Organic matter	3·10
Saline matter	9·30

1000·00

The organic matter probably consisted in part of albumen in combination with soda. The saline matter was principally composed of chloride of sodium; it contained, also, a

minute quantity of earthy phosphate, a trace of alkaline sulphate, and some alkaline carbonate. This specimen of ascitic liquid is exceedingly interesting in containing only an extremely small quantity of albumen.

These analyses are merely approximations to truth, and are probably sufficiently accurate for physiological and pathological considerations. The indeterminate organic matter is always a source of perplexity, and evidently undergoes changes during the analytical manipulations. The phosphoric and sulphuric acids found in the incinerated residua are derived by oxidation during the process of incineration of the sulphur and phosphorus existing in the albumen. Consequently, we have a source of error arising from the addition of oxygen to these elements.

[To be continued.]

RECORD OF CASES.

By THOMAS MAYO, M.D. F.R.S.

Physician to the Infirmary of St. Marylebone.

(For the *London Medical Gazette*.)

[Continued from page 542.]

It has been remarked by Dr. R. Willis, in an Essay on Malformation of the Heart, relatively to cyanosis, that "the only explanation that could be given of the absence of cyanosis in certain cases, in which imperfections of the auricular and ventricular septa have been discovered, would be grounded on the accurate maintenance of the proportion between the powers of the heart and the resistance which it has to overcome." The following case is one in which this conservative principle had acted probably under greater disadvantages, for a longer term of years, than have usually been adduced in the records of such cases.

Mary Thackeray, a stout tall woman, came into the St. Marylebone Infirmary on the 3d of December, 1841. She described herself as labouring under an habitual winter cough; said that, about a year ago, she had an acutely painful swelling of the great toe, and that she is subject to sudden difficulties of breathing, obliging her to jump up when prone at the time of their occurrence. The pulse was small and quick. Examining the thorax, I found considerable cardiac impulse and thumping, dulness over a large space in the cardiac region, and loud systolic bruit at the apex. In repeated examinations I found, beside the above symptoms, occasional large crepitation, principally above the base of the right lung, with deficient vesicular penetration at that part. The

sputa, on her coming into the infirmary, were mucous and rather tenacious; they became somewhat rouillées and mucopurulent, and then lost their tenaciousness. A slight attack of pneumonia was occurring at that time, which was obviated by leeches, a blister, and the following expectorant mixture:—

Misturæ Tragacanth Co. ʒij.; Potassæ Nitrat. ʒj.; Tincturæ Camphoræ, ʒss.; Tincturæ Scillæ, ℥xxv. Cæquâque horâ sumend.; with Pil. Scillæ c. hydrarg. bis quotidie.

On the 23d of December I find it noted by me, that the dyspnoea was then trifling, but that cough came on irritably when the patient was recumbent and her head low. But on the night of the 24th she underwent a severe fright from the violence of another patient in the ward. Much fluttering at the heart ensued on this; and then first the visage took a very purple hue. It was observed also by her that the urine, always rather deficient in her, then became more so. The above mixture was now changed for—

Misturæ Ætheris Co. ʒiss.; Vin. Ipecac. ℥xxv.; Tincturæ Humuli, ʒss. ter.

And she became, on this plan, more easy and composed; but the cyanosis remained unaltered. On the night of the 28th of December she had taken—

Misturæ Camphoræ, ʒiss.; Liqueur Opii Sedativ. ℥xxv.

And had settled comfortably to sleep. At 4 o'clock the next morning she died suddenly.

A perusal of the autopsy of this case may perhaps suggest the remark, that this woman's circulation was in an unfit state for opium; that its sedative effects may have been too great.

The contents of the cranium were normal. The heart weighed 18½ ounces. The right auricle was large; its muscular substance well developed. The right auriculo-ventricular opening was also large, but tolerably proportioned to the tricuspid valves. These valves, rather larger than usual, were white and thickened, particularly near the free edges; their columnar carnae were remarkably developed. The right ventricle was extraordinarily large, and its walls from three to four-eighths thick; the columnar carnae well marked; the semilunar valves of the pulmonary artery perfect. The left auricle was large and fleshy, thicker than the right; there was an open communication between it and the right auricle in the situation of the foramen ovale, extending an inch and a quarter from below backwards, and half an inch in the opposite direction. Two membranous bands, extending from the upper

to the lower portion of the auricle, divided this opening into three unequal parts. The left auriculo-ventricular opening was normal; the valves ill formed. The under mitral valve almost atrophied; the upper enormously large, about an inch and a half long, and broad in proportion. The left ventricle was greatly hypertrophied; the columnæ carneæ large. The pulmonary artery and veins were greatly distended and thickened, and were less supple in their coats than usual. The lungs exhibited a few points of semi-cartilaginous hardness at their summits; they were congested with blood, and somewhat œdematous, but everywhere crepitant. The liver large, of the nutmeg character; its weight 64 ounces. The kidneys were small. The other abdominal viscera were normal; as was the brain.*

In this monstrous case of perforate foramen ovale, the patient had attained her 57th year, a strongly made and not unhealthy woman, entirely free from the purple hue which belongs to a circulation thus rendered imperfect. In what way, or by what immediate agency, that arrangement was destroyed, which gave, for the most part, a right course to the respective volumes of blood, when the sudden fright incurred by the patient occasioned an unfavourable turn to her symptoms, and what was the immediate cause of death, are questions of equal difficulty and interest. One important practical consideration suggests itself in relation peculiarly to this case, and also to many others of less degree which have been collected,—that structural lesions, or diseases of a fatal nature, are not incompatible with prolonged duration of life. This consideration acquires increasing importance as medical science increases the catalogue of physical symptoms by which such lesions or diseases may be recognized. A disregard of it will produce a feeble and despondent use of medical measures, when abnormal states of a fatal tendency have been discovered; and thus the march of pathology will interfere with, instead of promoting, that of therapeutics.

The following case may strengthen this argument, by also presenting a long duration of cardiac mischief, though of another kind, which was at last apparently rendered fatal rather by the intemperance of the patient than the nature of the disorder.

* The preparation was put up by Dr. Boyd; and is at the Marylebone Infirmary.

Joseph Smith, aged 32, brewer's drayman, was admitted into the Marylebone Infirmary, September 26th, 1842. He was a stout, fair, sanguine person, and was, throughout, of a very placid, tranquil, enduring manner; he confessed that he had been intemperate. Came in under intense dyspnoea; visage purple, dilated; sharp and strong impulse of a struggling kind at apex of heart; its diastolic sound scarcely perceptible. His tongue dry, and very foul; urine scanty, not passed without catheter, very high coloured, abdomen distended; legs œdematous; coffee-ground vomiting; very low pulse, the effective beats of which were about twenty in the minute. Conjunctiva, and visage generally, yellow. The urine was instantly set free in this case, and the dyspnoea sensibly relieved by—

Acid. Hydrocyan. Dilut. $\mathfrak{m}\mathfrak{v}$. ex Haust.
Efferves. 8vis. horis.

Which was equally effectual in the first of these points ever afterwards. I should observe that I gained but little history with this man, except that he had had rheumatism severely many years before, but had been actively employed till within the last few weeks. His state, from his admission to his death, was as follows:—

The yellowness of conjunctiva and foulness of tongue gradually relieved, with much general improvement, principally noticed while he was under salivation from mercury. Afterwards, a mitigated recurrence of symptoms, gradually terminating in sleepiness, coma, and death, in about four months from the time of admission. Capability, at all times, of lying prone; coffee-ground vomiting recurred whenever his urine was suspended or materially diminished; the urine highly acid; no albumen.

Physical symptoms.—Breathing generally vesicular, but often with large crepitus. Dulness over a large cardiac space. Heart's action heard distinctly over every part of the thorax; but remarkably strong pulsation and impulse, as if immediately under the ear, at a defined point under the right clavicle; this, however, varying very much in relation to the application of leeches, by which it was always mitigated. Second sound of heart always inaudible. Alvine excretions generally healthy. Mind at all times perfectly collected, until coma supervened.

With respect to remedies, active purgatives, particularly Pulv. Jalapæ c. Hyd. Chlorid. was frequently given, and always with great relief. Also Olei Crotonis, gtt. j. often profited during the latter part of the case. Calomel was carried to salivation with great relief of dyspnoea. As diuretics, the hydrocyanic acid in an effervescing saline, and next to this the Mistura Ætheris c.

Scillæ of the Marylebone Pharmacopœia, with Tincturæ Lyttæ, $\mathfrak{m}\mathfrak{x}$ v. profited greatly.

He did not awake distressed, after taking, *horâ somni*, *Morphiæ Muriat.* gr. $\frac{1}{4}$, which was often thus given. Leeches occasional.

Autopsy.—Brain normal, except that it was exsanguine. Heart everywhere adherent to pericardium, but adhesions in many points soft; weight 22 ounces. Right ventricle normal; left, hypertrophied; valves normal, except that the edges of the aortic valves were thickened. Brachiocephalic artery much narrowed in calibre just before its bifurcation, and at the point in which the heart's impulse was heard so loudly. Lungs gorged, oedematous, not hepatised or tubercular. Liver very large, but healthy, as were the other abdominal viscera.

[To be continued.]

AN ACCOUNT
OF
PROF. MULDER'S RESEARCHES
ON
THE EXISTENCE OF OXIDES OF
PROTEIN IN THE BLOOD.

By GOLDING BIRD, A.M. and M.D.

Assistant Physician to, and Lecturer on Materia
Medica at, Guy's Hospital.

Previously known compounds of protein.
—*Formation of oxy-protein from albumen and fibrin.*—*Experiments on some products of inflammation.*—*Physiological inferences.*—*Theory of inflammation.*

PROFESSOR MULDER, of Utrecht, is well known for his discovery of protein, and of the series of compounds into which it enters. In continuing his researches into the nature of albuminous elements, he has been led to the discovery of some remarkable facts, which promise to throw much light over the obscure subject of the nature and composition of the products of inflammation. The following account of these researches cannot fail to be of interest to the physiologist, more particularly as no detailed account of Mulder's recent discoveries* has appeared in the English language.

A few years ago, Professor Mulder discovered, that when albumen, fibrin, casein, gluten, legumine, hair, or any of the varieties of animal or vegetable albuminous principles, were dissolved in a dilute solution of potass, a fluid

was obtained from which acetic acid precipitated a white flocculent deposit, which presented the same characters, and possessed the same composition, from whatever variety of albuminous principle it was prepared. This body he named protein, and regarded it as the essential constituent of the various albuminous products and tissue of the animal economy; the differences existing between these substances depending either upon one being more highly organized than another, or upon the presence of some portions of sulphur, phosphorus, oxygen, or the elements of water.

According to Mulder, protein consists of—

40	equivalents of carbon.
31	“ hydrogen.
5	“ nitrogen.
12	“ oxygen.

Fibrine of blood consists of—

10	equivalents of protein.
1	“ sulphur.
$\frac{1}{2}$	“ phosphorus.

Casein consists of—

10	equivalents of protein.
1	“ sulphur.

Middle coat of arteries consists of—

1	equivalent of protein.
2	“ water.

Animal mucus (of the gall-bladder) consists, according to the recent researches of Dr. Kemp, of—

1	equivalent of protein.
3	“ water.

And a similar composition has been lately assigned, by Dumas, to vitelline, the albuminous element of the yolk of egg.

The new discoveries of Professor Mulder consist in the detection of two compounds of protein, or its elements, with oxygen, and the announcement of the existence of these two oxides in the blood. He has also offered some speculations regarding the part played by these compounds in producing certain of the phenomena of inflammation. These oxides consist of—

A dextoxide = 1 protein + 2 oxygen.
And of a tritoxide = 1 protein + 3 oxygen.

The first of these compounds is soluble, and the second insoluble, in water. When speaking of these compounds as contemporaneous products,

* *Annalen der Chemie und Pharmacie*, Band 47, Seite 300.

Mulder uses the generic term *oxy-protein*.

It has been long known that fibrin and albumen, however pure, will, by long boiling, yield to water a considerable proportion of soluble matter: this has generally been regarded as gelatine, into which the fibrin or albumen was presumed to have been converted. M. Bouchardat has shewn that no evidence of the formation of gelatine can be obtained in the water with which fibrin has been boiled; but the buffy coat of inflamed blood, which has been generally regarded as consisting chiefly of fibrin, has been stated by this excellent chemist to contain gelatin.

Formation of oxy-protein from albumen and fibrin.

A. When fibrin or albumen, obtained from either healthy or inflamed blood, or coagulated white of egg, is boiled in water for four hours, the fluid being decanted, replaced by a fresh portion, and again boiled for the same length of time, and so on, the matter submitted to experiment is resolved into two portions; one which dissolves in water, and the other which remains insoluble. Both these contain less carbon, hydrogen, and nitrogen, than fibrin or albumen, but more oxygen; consequently an absorption of the latter must have taken place during the boiling. The watery solutions, when evaporated to dryness, leave an extract which is partly soluble in alcohol: this portion is the result of a true decomposition, or metamorphic change, of part of the protein; whilst the part insoluble in water, and the matter dissolved by the latter, but left unacted upon by the alcohol, are the results of a simple oxidation.

B. Some fibrine of ox's blood was boiled after being well washed for four hours; the filtered fluid was evaporated to dryness and digested in alcohol; the undissolved portion was dried, and, on analysis, gave the results shewn below (1). The portion undissolved by the water, after digestion in alcohol, was also dried and analysed; its composition is shewn below (3).

Another portion of fibrin was boiled in a Papin's digester for some days; the soluble portion, after digestion with alcohol, was, on analysis, found to be constituted as shewn below (2); and the composition of the part unacted upon by the water is shewn in column 4.

	Dissolved by the water.		Undissolved by the water.	
	1.	2.	3.	4.
Carbon	51.69	51.84	53.69	53.72
Hydrogen	6.64	6.78	6.90	6.73
Nitrogen	15.09	15.67	15.63	14.82
Oxygen	26.58	25.71	23.71	24.73

C. Albumen of white of eggs was boiled for 150 hours in water; oxygen was absorbed, and the albumen was converted into two portions, a soluble and an insoluble matter; these, when freed from metamorphic products by digestion with alcohol, were submitted to analysis, and found to possess the following compositions:—

	Dissolved by water.		Insoluble in water.	
	(1.)		(2.)	
Carbon .	51.38	.	54.99	.
Hydrogen .	6.78	.	7.16	.
Nitrogen .	15.01	.	15.33	.
Oxygen .	26.82	.	22.52	.

The soluble substance resulting from the oxidation of protein is thus shewn to be precisely identical by ultimate analysis whether obtained from fibrin or albumen, by long or short ebullition. A difference only exists in the composition of the matter undissolved by water when albumen of egg is substituted for fibrin of blood.

D. If the buffy coat of inflamed blood be boiled for a short time in water, and the matter dissolved be submitted to the test of analysis, it is found to be constituted exactly the same as the soluble bodies formed by oxidation of albumen and fibrin by boiling (B, C).

To this body Mulder assigns the formula $C_{40} H_{32} N_5 O_{16}$ and the per centage compositions calculated from this approaches closely to the results of analysis (B, 1, 3; C, 1).

40 equivalents Carbon	= per cent	51.45
32 " Hydrogen	= "	6.72
5 " Nitrogen	= "	14.92
16 " Oxygen	= "	26.93

This formula exactly corresponds to that of hydrate of tritoxide of protein.

	Carb.	Hyd.	Nit.	Ox.
1 Equivalent of Protein	= 40	+ 31	+ 5	+ 12
3 " Oxygen	=			3
1 " Water	=		1	1
	40 + 32 + 5 + 16			

E. The tritoxide of protein may be conveniently prepared by passing a current of gaseous chlorine through almost any albuminous fluid, as serum of blood: a dense white precipitate falls,

which consists of 1 Protein + 1 Chlorine + 3 Oxygen; when this is digested with ammonia, the chlorine is removed, and a hydrated tritoxide of protein left. (Pr. $O_3 + H O$).

The tritoxide generally contains an atom of water, unless combined with a metallic oxide, and then it is displaced by the oxide, the compound being precipitated in combination with undecomposed hydrate of tritoxide of protein. The general formula for these double combinations is (Pr. $O_3 + MO$) + (Pr. $O_3 + HO$). MO standing for the metallic oxide, and Pr assumed as the symbol of protein.

F. Tritoxide of protein is soluble in cold water, insoluble in alcohol, ether, or oils; it does not affect litmus or turmeric paper; it is very soluble in solution of the alkalis. The nitric, sulphuric, hydrochloric, phosphoric, and tannic acids, precipitate the tritoxide from its solutions. Bichloride of mercury, as well as both neutral and basic acetate of lead, throw down insoluble combinations of protein from its solution (as double salts?). When a solution of acetate of lead is added to one of tritoxide of protein, an insoluble combination (Pr $O_3 + Pb, O$) + (Pr $O_3 + H O$) falls). The acetic acid then set free holds more of this compound in solution, which falls on the addition of ammonia.

G. The composition of the insoluble matter into which fibrine is converted by ebullition with water may be represented by the formula $C_{40} H_{31} N_5 O_{14}$ which, when reduced to per centage composition, corresponds very closely with the actual results of analysis, (B, 3, 4).

40 equivalents	Carbon	= per cent.	53.36
31	Hydrogen	"	6.75
5	Nitrogen	"	15.45
14	Oxygen	"	24.44

Matter soluble in water	0.203	(tritoxide of protein?)
" insoluble "	1.220	(binoxide? fat, &c.)
Water	7.266	

8.689

The aqueous solution is perfectly free from gelatine.

M. From the experiments of Von Baumhauer, it appears that buffy coat of inflamed blood yields to ether 3.876 per cent. of fat, and to this he attributes the floating of the buffy coat on the surface of coagulating blood.

This matter is identical with the substance obtained by Van Laer and Scherer by digesting hair in caustic potass, and precipitating with an acid. It is a binoxide of protein; for

C. H. N. O.

1 equivalent Protein	= 40 + 31 + 5 + 12
+ 2 " Oxygen	2

$$= \text{Binoxide (Pr, } O_2) = 40 + 31 + 5 + 14$$

H. Exceedingly diluted hydrochloric acid rapidly converts fibrin into a gelatinous mass nearly all soluble in water, whilst it has scarcely any action on coagulated albumen. The addition of ammonia to the acid solution of fibrin precipitates an anhydrous tritoxide of protein. This has been termed *albuminose* by Bouchardet. The small portion undissolved by the hydrochloric acid (*epidermose* of Bouchardet) is probably binoxide of protein according to Mulder.

I. Coagulated albumen differs from fibrin essentially in the manner in which it undergoes oxidation by ebullition with water. Albumen is converted directly into soluble tritoxide of protein, the undissolved matter being unchanged albumen (C 2). Fibrin, however, is converted first into an insoluble binoxide, and subsequently into the soluble tritoxide.

Experiments on the products of inflammation.

K. When fresh buffy coat of inflamed blood is digested in water, it is divided into two portions—a soluble, consisting of tritoxide of protein, and an insoluble part, consisting of binoxide of protein and fatty matter.

L. 8.689 grammes of buffy coat of pleuritic blood contained—

N. When blood is heated sufficiently to coagulate its albuminous ingredients, digestion with water removes much tritoxide of protein, which can be precipitated by salts of lead and mercury.

It is obvious, that the serosity of Dr. Bostock, which exudes from coagulated serum, the muco-extractive matter

of Dr. Marcet, and the *extrait de viande* of Berzelius, consist chiefly of the tritoxide of protein of Prof. Mulder.

O. Falsemembranes (pleuritic?) were analysed eight years ago by Mulder, and he then gave the following as their composition.

Cellular tissue . . .	1.4
Fibrine . . .	28.6
Gelatine . . .	} 70.0
Extrait de viande . . .	
	100

In his late essay he remarks that the fibrine of this analysis is really chiefly composed of binoxide, and the gelatine and *extrait de viande*, of tritoxide of protein.

Chemico-physiological inferences.

1. False membranes, the result of serous inflammation, contain gelatine derived from the tissue on which they are formed: in other respects their composition is identical with that of buffy coat of inflamed blood.

2. The buffy coat is generated from the albumen of blood: it consists essentially of the two oxides of protein $\text{Pr O}_2 + \text{Pr O}_3 + \text{HO}$.

3. The buffy coat is formed in consequence of the excess of the two oxides of protein in the blood; and its floating upon the surface simply depends upon its levity from its presence of nearly four per cent. of fat.

4. When moist fibrin is exposed to the air it absorbs oxygen, and forms a certain quantity of carbonic acid gas. In consequence of this change all the published analyses of fibrin are regarded by Mulder as containing too little carbon, hydrogen, and nitrogen.

5. The two oxides of protein always exist in certain proportion in the blood; they are generated in the lungs during the process of respiration. By this oxidation the protein becomes the means of conveying oxygen to the tissues in the arterial blood. Mulder regards the oxy-protein as the true carrier of oxygen: he considers Liebig's idea of the red globules performing this function as quite unsatisfactory.

6. During inflammation and fever, a large excess of oxy-protein is generated, and may be found in the blood.

7. During the cooking of meat, whether by roasting or boiling, oxygen is absorbed: the fibrinous elements are converted into both oxides of protein;

whilst the albuminous matters are only partly changed into tritoxide.

Theory of the connection between the presence of oxy-protein and inflammation.

The change of protein into its oxides, which, as we have seen, is believed by Mulder to take place, during the action of the oxygen of the air upon the blood from the right heart during the process of respiration, is under certain circumstances considerably increased. The respiration becoming more rapid, a larger proportion of oxy-protein is generated, and ultimately the blood is so loaded with it, that on being removed from a vein a dense crust of the two oxides of protein mixed with fat floats on the surface, forming what is denominated the buffy coat, or inflammatory crust.

The pathological condition denominated fever is supposed by Mulder to be cotemporaneous with the development of more oxy-protein than in health; and when a large excess of this matter is collected, all the phenomena of inflammation are developed, and these compounds of protein are effused as inflammatory products (false membrane, lymph, pus, &c.)

Whilst Mulder agrees with Liebig, in the opinion that an increased absorption of oxygen exists during fever and inflammation, he altogether differs from him regarding the element which acts as the absorbing agent. Liebig, as is well known, assumes that the red particles absorb oxygen, the iron existing in them being changed from protoxide to sesqui-oxide; a view based on mere assumption, and totally unsupported by any evidence derived from chemical analysis. Mulder, on the other hand, having demonstrated the existence of two compounds of protein with oxygen, and having, moreover, shewn that the existence of these bodies in the blood actually gives it the appearance long ago assumed as characteristic of the presence of inflammatory action, in addition to the fact that the very matters effused as inflammatory products are chiefly composed of these oxides, has certainly very considerably advanced our knowledge of the chemistry of inflammation.

Mulder further attributes the metamorphosis and removal of effete tissue

(destructive assimilation), to the influence of oxygen, as Liebig does, but not to the oxygen conveyed in the red particles, as imagined by the latter chemist. On the contrary, he supposes that the oxy-protein generated during respiration in the arterial blood, reaches the capillaries; and whilst the protein is deposited where new tissue is required, the oxygen previously combined with it oxidises and re-arranges the elements of effete and exhausted structure into a form fit for their removal in a state of solution.

Mulder offers no speculation regarding the origin of fever; he evidently regards its presence as the pathological condition which induces the generation of oxy-protein, but regards the existence of the latter in the blood as the cause of the development of the phenomena of inflammation.

These speculations are of peculiar interest in these days of humoral pathology, and have the advantage of being supported by experiment to a much greater extent than the analogous hypotheses of Liebig. They are deserving of great attention, but, like all chemical theories of health or disease, should be admitted with caution, as a more melancholy error can scarcely be committed than that of explaining the phenomena of the animal organism too exclusively on chemical principles.

ON A PECULIAR AFFECTION OF THE EYEBROWS.

To the Editor of the Medical Gazette.

SIR,

I SEND you the following observations, in the hope that their publication may be the means of obtaining from others additional information on the subject of which they treat. Should this object appear to you sufficient to justify their insertion, you will oblige me by giving them a place in the pages of your valuable journal.—I am, sir,

Your obedient servant,

GEORGE ROBINSON,

Fellow of the Royal Medical and
Chirurgical Society, &c.

21, City Road, Finsbury Square,
January 31st, 1814.

There are many affections which, without being dangerous to life, are in themselves sufficiently inconvenient,

and become still more unpleasant by the effects to which they subsequently give rise. Among the extensive group of minor ailments to which we are subjected, none perhaps are regarded with more solicitude by the great mass of mankind than those affecting the integrity and expression of the countenance.

Having, by a conjunction of favourable accidents, been enabled to detect one, and probably a chief, cause of that partial or complete destruction of the eyebrows and eyelashes, instances of which are not unfrequently observable in all ranks of society, I shall now proceed to narrate the circumstances which led me to its discovery, in the order in which they occurred to me.

In the summer of 1842 I happened to meet with a lady who had lost the greater part of her eyebrows and eyelashes, and was thereby very much disfigured. When questioning me as to the possibility of the growth of hair ever being re-established, she communicated to me the history of her case, the substance of which may be thus stated. The complaint was first observed about ten years previously, viz. in the autumn of 1832 or 1833, when the eyebrows gradually became so much detached from their connection with the skin that, each time the face was washed, some half-dozen adhered to the towel. An intense itching of the skin covered by the eyebrows was then also, for the first time, remarked. This sensation became almost intolerable on entering a warm apartment, or on applying to the part any warm or stimulating substance. This irritability of the skin, doubtless occasionally aggravated by instinctive attempts to relieve it by friction, caused the integuments of the eyebrows constantly to assume a fiery red colour.

From the peculiar sensation accompanying this symptom, the patient felt convinced in her own mind that it was occasioned by the lodgement of some minute insect in the skin of the affected part; and she mentioned this idea to various medical men whom she consulted. These gentlemen all treated the supposition as chimerical; though her ordinary medical adviser informed her that he had met with many similar cases, in which the eyebrows, eyelashes, and in one instance the whiskers of a

military gentleman, had fallen off without any assignable cause; the complaint having, in all of them, been preceded and accompanied by the same symptoms of intolerable itching, and intense redness of the skin of the affected parts. He ordered the hair of the eyebrows to be shaved off, and the skin to be frequently washed with cold water. The other gentlemen who were consulted recommended various local applications; but, if I may judge of their views of the pathology of the complaint from the prescriptions which were shewn me, they appear to have considered it as symptomatic of some intestinal disorder, for which various alteratives and aperients were ordered. One physician recommended a blister to be applied behind each ear: but the pathological views which suggested this remedy are to me quite unfathomable.

At length, after enduring the annoyance of the complaint during a period of four years, and being tormented during the whole of that time by numberless local applications, the chief effect of which was a momentary increase in the irritability of the skin, the morbid sensation and the loss of hair gradually ceased, and have never since returned.

Continuing throughout unshaken in her belief as to the real cause of the disorder, the patient had carefully preserved every minute object that was perceptible on the skin between the insertion of the hairs, or that adhered to the latter after their removal. Among these particles she fancied some were of a more regular form than the rest; harder to the touch, and apparently somewhat oval in their shape. The attention of her medical attendant was directed to them; but they were too minute to afford any other than a very indistinct idea of their nature to the naked eye. He, therefore, again assured her that her idea was in reality entirely unfounded.

At a subsequent period, after she had ceased to have medical advice on the subject, an object much larger, though still too minute to be clearly distinguished in all its parts by the naked eye, was detected among the lighter coloured particles. This object, together with a quantity of particles collected from the same source, and which had been carefully preserved

during the intervening period, were presented to me at the time I received this history.

On examining the whole of these particles under the microscope, I found, as might be expected, the greater part to consist of minute portions of epidermis, the scales of which were matted together, and slightly stained by a bloody serum. But with these there were also distinctly visible two bodies, which, from their shape, and from the firmness with which they preserved it under pressure, were evidently the ova of some small insect. In one of them the process of development had already commenced; for on it were seen six minute protuberances, the relative position of which indicated them as rudimentary legs.

The larger and darker object, though slightly mutilated in consequence of the great length of time during which it had been preserved, was nevertheless sufficiently perfect to enable its nature to be satisfactorily ascertained; and it presented all the characteristics of a fully developed insect. Its body, oval in form, was much wider posteriorly than anteriorly; the legs, six in number, were chiefly remarkable for being long, flexible, and tapering. It should be remarked that this was the only perceptible insect that was ever obtained from the eye-brows: though the minute oval bodies were not unfrequently met with. Having thus satisfied myself as to the existence of two ova in these particles, and a full-grown insect having been obtained from the same source, I could not but believe in the possibility of the disease in question having been occasioned by the lodgement of these insects in the skin of the affected part. The irritation caused by their presence there would readily account for the symptoms of redness and itching; and the subsequent inflammation would inevitably tend to weaken the attachment of the hairs to the subjacent skin.

On consulting some books, I could not find that this affection had been described by writers on diseases of the skin; nor, among the various figures of insects said to infest the human body, could I perceive any which corresponded precisely with that in my possession. As I intended to investigate the nature and source of these insects at some future opportunity, I deferred publishing any account of this observa-

tion, till its truth should be fully established by additional facts. The subject has thus been allowed to remain dormant for a few months, when my attention was again suddenly directed to it by the accidental discovery of the same insect on the body of the common house-fly. This circumstance occurred late in the autumn of the same year, when happening to place a fly under a microscope, I perceived two insects fastened to its body. On detaching them, I found to my utter surprise that they precisely resembled the full-grown insect from the eye-brow; the shape of which had, from frequent examination, become quite familiar to my eye. On subsequently placing it by the side of these living insects the resemblance was most perfect.

In the course of last summer, about the month of July, I resumed my observations on the flies, in order to satisfy myself that they were extensively infested with these insects; and I had not examined half a dozen before I met with some specimens precisely similar to the last. I had also the satisfaction of speedily obtaining from the same source more than a dozen young insects the size, shape, and colour of which tended still further to strengthen my opinion as to the identity of the insects infesting the fly and the human skin: for their bodies were perfectly oval in their shape, and of a light colour approaching to greenish-yellow, in both which particulars, as well as in size, they so closely resembled the ova which I first examined, that, had the latter been furnished with their proper legs and antennae, it would have been impossible to distinguish one from the other.

I have unfortunately, from neglecting to secure them properly, lost the whole of these young insects; but I now possess the full-grown one from the eye-brow, the two obtained from the fly in the autumn in 1842, and six similar ones secured last summer: I should have sent the proper name with this communication, but have been disappointed in obtaining it. But as it is probably familiar to entomologists, and a supply can readily be obtained in the proper season of the year, this omission may be considered of the less importance. It is almost unnecessary to point out the facility with which these volatile carriers of vermin may deposit one of these undesirable companions on

a part of the body so much exposed, and so retentive of extraneous matters, as the eyebrows. And it is also evident that the greatest attention to personal cleanliness may fail to protect an individual from this infliction.

The chief practical points on which the foregoing observations bear, are the following:—

1. The prevention of the complaint.
2. The symptoms distinguishing it when fully formed.
3. Its treatment.

It is evident that the prevention of the disorder can only be effected by guarding against the visits of those winged tormentors which convey its cause. But in the early part of a hot summer's morning, they may, during sleep, lodge upon the face unseen and unfelt, and thus originate the complaint. Perhaps, the best preservative, in addition to general cleanliness, would be afforded by regularly brushing the eyebrows, night and morning, during the summer months. For the full-grown insect is sufficiently large to be removed by a brush; and if any had lodged there during the preceding interval, they might, in this manner, be swept away before depositing their ova in the skin. And that the fully developed insects can be thus displaced is rendered probable by the fact, that during the four years the complaint existed in the case here detailed, only one full-grown specimen was met with.

The symptoms appear to be sufficiently striking. Whenever, during the heat of summer or in the autumn, a violent itching of the eyebrows, or any other part of the face covered with hair, is felt for the first time, accompanied by an intense redness of the subjacent skin, and followed by a gradual loss of the hair, these symptoms will, I think, generally be found connected with the existence of the peculiar cause above mentioned. I have occasionally in various public places had my attention directed by the symptom of redness alone to the eyebrows of several individuals; and the loss of hair was generally very obvious.

As to the treatment, the chief indication is clearly the removal of the cause: but this would seem not to be very easily effected. For so long as the ova are deposited, either in the skin itself, or at the point of insertion of the hairs into it, some difficulty must be ex-

perienched in finding a substance that shall at once eradicate the cause of the complaint. In the case above mentioned, the local applications appear to have been very numerous and diversified. Thus vinegar, spirit of camphor, mercurial ointment, tobacco infusion, were with many other remedies tried ineffectually. And whatever treatment be adopted, it must evidently be continued for some time before a perfect cure can be obtained.

I shall not at present add more than a repetition of my wish, that these remarks may be the means of directing the attention of others to the subject, and may thus elicit further information.

I cannot, however, avoid mentioning two questions which were suggested by the facts here detailed, viz.

1. To what extent are the parasitical insects affecting the exterior of the human body, that of scabies for example, identical with, and derived from, those infesting the bodies of certain of the lower animals?

And secondly, are not several, if not all the forms of pruritus—complaints of the incurability of which I have more than once observed, in the pages of this and other medical journals—occasioned by the lodgement of some minute parasitical insects in the skin, and not by mere inanimate dirt?

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégér.”—D'ALEMBERT.

On the Nature and Treatment of Tic Douloureux, Sciatica, and other Neuralgic Disorders. By HENRY HUNT, M.D. &c. 8vo. pp. 204. London, 1844.

THE author remarks, with some justice, that the object of the majority of those who have written on tic douloureux has rather been to advocate the efficacy of some favourite remedy, than to inquire into the nature and causes of the malady. The result has been a somewhat empirical treatment; various remedies having had for a time a reputation above their merits, and then fallen into disuse. Carbonate of iron, bark, and arsenic, may be taken as illustrations. Dr. Hunt having practised in the south of Devon, where the

disease appears to be common, has had ample opportunities of studying it; and he has been led to conclude that it has its origin in different persons from dissimilar causes, and opposite conditions of the system.

In the work before us he has selected cases in illustration of this principle, and arranged them under corresponding heads; to which he has appended some observations, and a detail of the means which he found most efficacious in the cure.

We have first a general description of tic douloureux, and then follows an account of the disease in different forms, as the tic from neuralgic habit—from dyspepsia—from congestion of the liver and other viscera. After this our author proceeds to describe the disease as dependent upon anæmia—from disease of the spine, brain, uterus;—that from mechanical causes, and from the retrocession of eruptions. Sciatica and periodical headache also come in for their share in the discussion.

The general description of the disease contains nothing remarkable, but is a very fair account of the phenomena which usually present themselves. The author remarks, that the intensity of the suffering does not in any degree depend upon the particular cause which has produced it, but upon other circumstances connected with the peculiarities of the individual. Upon the whole, the portion of the work which relates to tic douloureux connected with indigestion is the most interesting, and may be taken as a very good illustration of our author's views and mode of handling his subject.

A considerable variety of nervous affections are unquestionably dependent upon the state of the digestive system; although it not unfrequently happens that no particular distress is experienced in any of those viscera. The immediate effect sometimes produced on a distant part by the condition of the stomach is well illustrated by a reference to the case of Dr. Wollaston, who was suddenly seized with pain in the ankle from eating an ice; which was relieved the moment the stomach was emptied by the act of vomiting. Dr. Hunt gives a case in illustration of the same principle; and as it is an instructive one, and not very lengthy, we subjoin it:—

"The very Rev. Dean of —, a gentleman who had enjoyed unusually good health, finding himself inclined to grow rather too stout, although he was arrived at a period of life when such a tendency not unusually shows itself, imprudently altered his plan of living: after having lived generously, and having taken little exercise, he adopted suddenly a very spare and abstemious diet, accompanied at the same time by excessive walking exercise, by which he was reduced to a state of great general weakness. The tone of his stomach was very seriously injured, and unequivocal symptoms of indigestion, and among them the presence of acid, were the result.

"After a few weeks he perceived an uneasiness in the cheek; this increased in severity, and he was seldom free from pain, but it was much aggravated every night about eleven or twelve o'clock, then almost amounting to a distinct paroxysm. He applied to me in August, 1837: his general strength at this time had been much improved, for he walked eight miles to see me, and had the same distance to return home. The stomach also was somewhat improved, but still weak. He had constant pain in the cheek, which was much increased on pressure, making the operation of shaving a very painful one. The imperfect paroxysm of pain continued every night four or five hours, accompanied by severe shocks and plunges. There was no indication of the disorder of the stomach having extended to any other viscera; his tongue was slightly furred, and was a little swelled; the bowels very regular, and the evacuations healthy; the appetite was good, but the digestion was still imperfect. After an emetic and aperient draught of rhubarb and sulphate of potash, warmed with sal volatile, I gave him the following draught three times a day, an hour before his meals:—

R Liq. Arsenicalis, ℥iv.; Tr. Camph. comp. ℥xij.; Aquæ Cinnam. 3x. M. ft. haustus;

increasing the quantity of the liquor arsenicalis daily, until he felt its action on the stomach, which he did when each dose amounted to twelve minims; it was then discontinued. As soon as he perceived the effect of the medicine, the violent plunges of pain diminished, slowly but regularly, until at the expi-

ration of a fortnight they had altogether ceased. By this time the action of the arsenic had also subsided; he again took it in doses of five minims, and continued it till all tenderness and pain of the cheek was entirely overcome. This was effected at the expiration of a month from the time of my first seeing him. He then left my neighbourhood, with directions to take the medicine for some months, occasionally omitting it for a fortnight or three weeks, increasing gradually the interval, and decreasing the period, in which he took it.

"In January following I received the following account from him:—'Since I left your neighbourhood, I have had only two returns of tic, and those very slight; I think I continued to take your prescription in small doses for about a month, after my return to —, and having discontinued it about a fortnight, I had a slight return of the spasmodic pain, which yielded immediately to the arsenic. On this occasion, I took it in still smaller doses, only twice a day, and not exceeding three drops at each dose. After about three weeks, I again discontinued it, and at the end of another fortnight had a slight attack of tic, which yielded instantly to your prescription, which I took in the same small doses for a fortnight, and for the last month I have been quite free from pain, though I suspect that the nerve is not quite sound, from a feeling of numbness and tingling, which I used to regard as a precursor of an attack.'

"After this time, the pain seldom troubled him, and only when his stomach became disordered.

"In 1841 he wrote me that by strict attention to diet, and above all, by abstaining from acids, and from the use of wine, and other fermented liquors, he kept the tic from annoying him.

"In this case many remedies had been taken without any mitigation of the pain, but with rather an aggravation of it."

In that form of the malady which results from disease of the spine, sudden and complete mitigation of the pain sometimes occurs on the application of the caustic; but in other instances even this fails to give any relief.

Disease of bone, where a nerve passes

over it, sometimes proves the source of very obstinate and severe neuralgia; and it is remarkable that the tic dependent upon the uterus seems to come next in succession in these respects.

Several very good cases are given of tic dependent upon local mechanical causes.

In his account of the various remedies applicable to neuralgia, a considerable space is devoted to the use of sedatives, which, our author remarks, are given in various ways, viz. in large doses at once; in comparatively small ones gradually increased; or in ordinary doses frequently repeated. Of these methods Dr. Hunt thinks the first the worst, and the last the most eligible; for example, giving the largest ordinary dose at short intervals, as every two hours, and in very urgent cases every hour, for three or four doses. In this manner our author has never seen any unpleasant symptom produced by sedatives. Relief having once been effected, a much smaller dose will be found sufficient to keep the pain under control. Belladonna is the narcotic which, in our author's hands, has most frequently answered, and the largest quantity he has administered "has not exceeded one grain for three successive hours." The sedatives must speedily be followed by some mild aperient, to guard against the risk of any accumulation.

Arsenic has been found by Dr. Hunt to be very powerful in some cases; and not only useless but hurtful in others. It acts most favourably on those of lax fibre and languid circulation, with profuse secretions. In such patients it sometimes succeeds far better than any other medicine, but often requires a good deal of patience and management. Dr. Hunt states that he has met with several cases in which the disease has resisted the arsenic in solution, and has nevertheless yielded to it in the solid form. When administered in this way, the dose varies from the twentieth to the tenth part of a grain, which may be made into pills with crumb of bread, previously rubbing the arsenic in a mortar with a little black pepper, and taking especial care that it is accurately divided into its appropriate doses. In some rare instances the arsenic produces an eruption; and it would seem, so far as the evidence yet goes, that where this is

the case, it does not relieve the neuralgia.

The local remedies for neuralgia may be divided into two sets—sedatives and counter-irritants. Aconite, veratria, belladonna, and stramonium, are mentioned; and of these our author regards aconite as the most efficient. It produces a kind of paralysis of the part to which it is applied, and in this manner diminishes the sensibility of the nerve. When this passes away, the pain returns. The strength of aconite recommended by our author is a grain in a drachm of ointment. This is to be applied with the finger to the seat of pain, and gently rubbed upon it; the application to be repeated twice a day. Belladonna comes next in point of power, but the relief it gives is more temporary. A cataplasm, made of equal parts of linseed-meal and bruised stramonium seeds, is spoken of with praise. Veratria has always failed in Dr. Hunt's hands.

When the tic depends upon the state of the spine, the application of extract of belladonna to the back has sometimes been very serviceable. The proportions used were a drachm to two ounces of soap liniment. The effects are sometimes very powerful, and the remedy, therefore, requires considerable care in its use.

We are cautioned, in conclusion, that the treatment, both medical and general, often requires to be persevered in long after the pain has ceased, otherwise it is apt to return, even in cases which have been apparently cured.

Posthumous Extracts from the Veterinary Records of the late John Field.
 Edited by his Brother, WILLIAM FIELD, Veterinary Surgeon, London.
 London, 1843. Svo. pp. 236.

A SERIES of valuable contributions from the papers of a first-rate veterinarian. We can afford room for the following extracts only.

"Fracture of the bones of the knee.—A mare belonging to Mr. H. B., in an unprepared state, was run at Outlands, July 16, 1826, for a cup, heats. Though unfit to start, she won the first heat cleverly; but in galloping the second heat, suddenly stopped, and seemed ready to fall. The rider, Mr. St. Aubyn, dismounted, and the mare was with difficulty got to the stable.

"July 17th.—I saw her at Oatlands, and found the bones of both knees broken, particularly of the off. She stood up at times, and the knee-joints were bent outwards, forming bow-legs; but the principal weight was thrown upon her hind quarters: there was very little tumefaction.

"She was destroyed, and the bones sent to me: in one knee the seven larger bones formed sixteen pieces." (p. 37.)

"*Effects of tobacco infusion as a dressing for mange.*—Dec. 30th, 1817.—A horse, belonging to Colonel —, at Hall's Stables, in Grosvenor Place, was dressed over with tobacco-water in order to cure the mange; this was about nine o'clock in the morning, and at half-past twelve a man came to say the horse was extremely ill. When I went to the stables I found him breathing very laboriously, sighing, and shivering; there was no pulse to be felt; at least the pulsations were not distinguishable. I ordered the tobacco-water to be washed off with warm water and scrapers; I desired four drachms of purging paste to be given immediately, with the following drink:—

"R Sp. Æth. Nit. ʒss.; Tinc. Rhei. ʒij.;
Tinc. Zingiberis, ʒss.; Aquæ, Oj. Mis.

"A similar drink to be repeated in three hours if he was not better; but, if much improved, not till the evening.

"The horse was seen again in the evening, when his pulse was very irregular: there was no shivering nor blowing; he fed well; and the next morning he was perfectly recovered." (p. 57.)

publicum sit, dicendi periculum non recuso."

CICERO.

NEGLECT OF THE INSANE POOR IN SCOTLAND.

A LETTER on this important subject has been published not long ago in the Dumfriesshire and Galloway Herald,

845.—XXXIII.

and has since been reprinted in a different form. The letter is anonymous; but we have been favoured with the name of the writer, who is a physician, and the author of a well-known treatise on insanity.

The enactment of a poor-law for Scotland is now shortly expected; and never was there a land for which a poor-law was more wanted. From our comments on Dr. Alison's valuable works, our readers will have learned how very little is done for the indigent in Scotland. In short, no country ever existed which demonstrated more clearly the fallacy of the theory, that private charity can supply the place of a public provision for the poor. Nor is this proved only by the crowded wynds of Edinburgh or Glasgow, with their hordes of human beings rotting in a state below beggary; for the most secluded villages betray a similar spectacle to the inquirer—misery swept out of the way, but not relieved. The female field labourers, says Mr. Chambers, being unable to work after about 50, "inevitably become destitute, and depend, for the remainder of their lives, on the charity of their neighbours, or parochial allowance; the parish rarely offers to such persons more than 1s. per week. Individuals occasionally give them some scraps, but this succour is very trifling; the only chance for such persons seems to be an acute illness, for then some little attention is paid them."

Those who are acquainted with the appalling facts revealed by Dr. Alison will scarcely be startled by those contained in the Dumfries letter. They harmonize so well together; the chords that vibrate so feebly to the sufferings of the sane are equally sluggish to the sufferings of the deranged.

From the returns drawn up by the clergy in 1818, it appeared that there were then at least 310 lunatics in the

ounties of Dumfries and Wigtown, and the stewartry of Kircudbright; and 198 of these were at large. A later document, dated in 1831, states the total number of lunatics at 333.

Now, the two hundred who wander unrestrained are injurious in various ways to the public weal, and even infringe on the public safety. Some commit murder; some have the aspect, as well as the instincts, of satyrs; and others are worried into fury by the boys of their native villages. They thus teach that most undesirable of lessons, an indifference to the sufferings of others; until those who once sympathized with human pain become callous by habit, and learn to jest, as it has been beautifully expressed, in the sacred presence of misery. "Davie Gellatly must not be taken as a type of the race. They are no longer regarded with superstitious awe or forbearance."

In England, as we all know, every lunatic has his settlement; and should he unfortunately belong to a county which has no county asylum, he will be sent at the expense of his parish to a private one, or, at worst, he can claim a refuge in a workhouse. In Scotland, the law does not protect him until he commits some crime; he is then sent to a jail, or an asylum. Many lunatics, no doubt, are under the care of friends or relations; but, unfortunately, this is sometimes a very frail safeguard: insanity too often dissolves every tie of nature, and the relation is forgotten in the lunatic.

"Within a short period," says our Scottish fellow-labourer, "I have seen a maniac who, bound and galled, and cut by his bonds, had been crushed and confined in a small hole beneath a stair; where, although deprived of every means to inflict injury, and dependent on those who had shorn him of his former powers and privileges, he was shunned by his relatives as the plague-stricken were formerly shunned.

I know that at this moment there are lunatics immured in cellars, closets, lofts," &c.

In another case, a woman was locked up for nine months in a garret, deserted by those who had slept in the same cradle, and with her bed unchanged for weeks. Dr. — gives nine instances of grievous neglect or oppression occurring in a country town somewhat smaller than Dumfries, and collected in 1840. Here is one of them.

"A woman, still very young, has become completely paralytic in her limbs, from having been heavily ironed by her parents during a period of at least ten years."

He also shows that justice to the insane would be the truest economy. If left without treatment, nine-tenths of indigent lunatics will become chargeable for life as "impotent poor;" while, if properly treated, at least one-third will recover. We blush to think that it should have been necessary to use such an argument; and we should have been glad to leave it understood in the general formula, that the right is always the expedient; but since the *argumentum ad crumenam* reaches ears that are deaf to all others, it was perhaps as well to employ it.

As a remedy for these crying evils, he proposes to enlarge the present asylums at Edinburgh, Glasgow, Aberdeen, &c., thus saving the expense of new sites, and a fresh medical and domestic staff. But could the duties of these officers be doubled, with advantage to the insane and themselves? We doubt it. The common fault in hospitals, whether general or special, is, that each physician has too many patients; he sees the cases, indeed, but can hardly study them.

We therefore hope, that, wherever the existing asylum is already so large that additional wings would be a burden, a new one will be built for this formidable variety of human distress.

If justice and pity demand a poor-law, mere shame should be sufficient to extort a provision for lunatics.

SECRETS OF A UNION WORKHOUSE.

WE do not know whether the workhouse of the Nacton Union, in Suffolk, is worse managed than other similar establishments; or whether this house has merely had the ill luck to shelter a poor man not afraid to disclose the secrets of his prison-house; but certain it is, that this receptacle has come out of a recent investigation with a very shattered character. It seems that Thomas King, formerly a schoolmaster in other Unions, but lately a pauper in this workhouse, addressed a letter, on the 18th of January, to Mr. R. N. Shawe, Chairman of the Board of Guardians, desiring to be allowed to substantiate seven charges against the authorities of the workhouse. A copy of this letter having been transmitted to the Poor-Law Commissioners, they sent down Sir John Walsham, an Assistant-Commissioner, to investigate the case on the spot. The inquiry lasted three days, and the upshot of it was, that the Commissioners thought that the charges against the chaplain, surgeon, governor, matron, and porter, had not been substantiated, but that those against the nurse were established beyond all doubt.

One of the charges proved against her was that of causing a patient named Haggard to be tied down in his bed on the night he died. King stated that "the deceased, who was 76 years of age, was put in the sick ward on the 12th of January. The old man got out of bed several times in the night, and as he was very feeble, King and other patients assisted him into bed. There was neither fire nor candle in the ward. King called the nurse, and told her that the bed-clothes could not be kept on the patient. The nurse said, 'I'll

manage him this time, so that he shall not get out of bed any more.' King said, 'Why, nurse, the man is dying; you had better sit up with him;' to which the nurse replied, 'No, I'll manage him.' She then got a piece of rope, or window sash line, and asked King to assist her in tying the old man down in bed. The rope was passed round the bed-rail on either side, and over Haggard's body, in which state he was left. One of the paupers said, 'It would be better that you put it round the man's neck at once.' King went to the bedside early next morning. The man was then dead and cold."

King's testimony was corroborated by two paupers, one of whom gave as a reason for not complaining to the governor, that he had been told it was the rule of the house to tie patients down in bed, when troublesome. Another pauper mentioned the names of four patients who had died in the night under similar circumstances, not tied down with ropes, indeed, but unnursed and untended. Another case, which, if correctly stated in all its particulars, would be a dark one indeed, is that of Garrod, a patient eighty years of age, who died of abscess of the kidneys.

Not to mention other instances of alleged neglect, he appears to have lacked even clean linen. The regular visiting days of the surgeon occur only twice a week. We hope that his assistant attends on the other five; for it is so obvious that an infirmary requires the daily visit of a medical practitioner, that all argument is needless on the topic.

We will mention only one more anomaly in this house of irregularities. The assistant nurse, Ann Davis, who is frequently mentioned in the evidence, is imbecile; so much so, indeed, that, though called as a witness, she was not examined, owing to her deficiency of intellect.

Sir John Walsham condemned, in the most emphatic terms, the practice of tying patients in their beds; and censured the employment of a girl of weak intellect as nurse, adding that the doing so in the men's wards was indecent. Although he exonerated the governor and matron from the suspicion of having sanctioned the conduct of their subordinates, he thought they were indirectly culpable, in not having paid closer attention to it.

Mr. Shawe, the chairman, was not satisfied with the governor, and asked if dying men were to be left without any to sit up with them? "Nothing could justify such negligence."

In a word, though the breath of censure ruffled several other persons, the nurse alone will be the scape-goat for the rest.

She was unable to trim the balance with such nicety, as to keep up all the rigour of the workhouse test on one hand, and save appearances on the other. The whispered severity of her betters in her became open unfeelingness, and she will be sacrificed for carrying out their system.

The miser in "Old Mortality" thought a dipped candle good enough to die by, and this unfortunate nurse probably surmised, that, in the opinion of the board, a sick ward, without fire or candle, was good enough for the last hours of the poor of the Nacton Union.*

LECTURE

ON THE

CASES IN WHICH IT IS EXPEDIENT TO PERFORM THE OPERATION FOR THE REMOVAL OF SCIRRHIOUS TUMOR OF THE FEMALE BREAST,

Delivered in the Theatre of St. George's Hospital, January 24, 1844,

BY SIR B. C. BRODIE, BART.

GENTLEMEN,—If a scirrhous tumor of the female breast be left to take its own course

it gradually increases in extent; it contaminates the neighbouring textures; it finally ulcerates, and in the greater number of cases the patient's life is terminated in three or four years from the commencement of the disease. Not only is life terminated thus early, but death is preceded by a most painful state of the ulcer. It is disposed to bleed and to slough, and the patient is rendered miserable. There is not a much worse way of going out of the world than that of being destroyed by this disease.

Looking at these facts alone, you would say there is no doubt that the proper thing to do is to remove the tumor by an operation. But then there is another order of facts to be taken into account. We find that in the larger proportion of cases in which the operation is performed, the patient is not alive two or three years afterwards; and in a great many cases, instead of the operation stopping the disease, it actually seems to hasten its progress. We find, besides, that the operation in itself is not in all cases free from danger.

These different orders of facts have led different surgeons, accordingly as they have looked at one or the other of them, to come to different conclusions as to the propriety of the operation. The late Mr. Cline, for example, and Sir Everard Home, both men of great experience, would scarcely ever consent to the removal of scirrhous tumors of the breast under any circumstances; whereas I have known other very experienced surgeons who were in favour of an operation, even in the great majority of cases. And not only has there been this difference of opinion between different individuals, but I have known the opinion of the same individual to differ at various periods of his life. I remember a very distinguished surgeon saying to me that he thought he would never perform this operation again, and yet that very surgeon, some three or four years afterwards, recommended the operation in a case in which I thought that it would fail. This discordance of opinion only shows the difficulty of the subject; and if this difficulty has stood in the way of men of great experience, it may well stand in the way of you who are beginning your career. Hence, it appears to me, that it may be of advantage to you if I offer some observations on the subject, and endeavour, as far as I can, to clear away the doubts which may arise in your minds as to the expediency or the in expediency of the operation.

This, then, is the subject of the present lecture:—Under what circumstances is the operation for the removal of a scirrhous tumor of the breast proper, and under what circumstances it is improper?

I should observe here, in the first instance, that while a great deal depends upon the

* We are indebted for the account of this inquiry to the Times of February 5th, 1844.

nature of the case, something will depend upon yourselves, and upon the mode of performing the operation. If there be a scirrhus tumor imbedded in the gland of the breast, and you remove the tumor and a piece of the breast in which it is imbedded, and leave the rest of the breast, according to my experience the disease is quite sure to return; and this corresponds to a rule which applies to all cases of malignant disease—that you have no security from an operation for its removal, unless you remove the whole of the organ in which the disease is seated. If, for instance, there be *fungus hæmatodes* of the bone of the leg, the patient may have some chance of doing well if you amputate the thigh above the knee; and if there be malignant disease in the femur he has almost no chance, unless, indeed, you think it worth while to take out the thigh-bone at the hip-joint. I say, therefore, that in cases of scirrhus tumor of the breast, where the tumor is actually imbedded in the breast, if you perform the operation you must remove the whole of the breast. You may imagine that this is a very easy thing to be done, but it is not so easy in reality: for in amputating the breast, you will be very apt, in a thin person, if you are not very careful, to leave small slices of the gland of the breast adhering to the skin, and I have no doubt that the part or parts thus left behind in some cases form the nidus of future disease. The colour of the gland of the breast is very little different from that of the surrounding adeps; and the blood that flows adds to the confusion. To avoid the error in question, you must be careful in the dissection to keep the knife near the skin, not near the breast; and, further than this, in every case when you have taken out the tumor, you should look at its surface, and see that it is every where covered by healthy adeps. If it be not, then examine the inside of the flap of the skin, and see whether any small portion of the breast has been allowed to remain there.

So far, I say, the success of the operation may depend mainly on yourselves: but now let us consider what are the circumstances, independently of anything that you do, that may lead you to think there is no chance of the operation leading to an ultimate cure; and what are the circumstances that would lead you to hope that the result may be more favourable.

First, you may divide scirrhus tumors of the breast into two classes—one where there is a conversion of the gland of the breast itself into the scirrhus structure, there being no well-defined margin to it; the other, where there is a scirrhus tumor imbedded in what appears like a healthy breast, as if it were altogether a new growth, there being a well-defined boundary to it.

In the first order of cases, where the tumor has no distinct boundary, and where it is the conversion of the gland of the breast into the diseased structure, the operation not only never succeeds in making a permanent cure, but it rather hastens the progress of the disease. The patient dies within two or three years, and probably much sooner, from an effusion of fluid into the cavity of the pleura.

Then, where the skin is contaminated, there is no chance of the operation making an ultimate or permanent cure. The skin may be contaminated in different ways. Scirrhus tubercles sometimes form in it here and there, at some distance round the tumor, the intermediate portions of the skin appearing to be healthy. Here an operation will never lead to a cure, for you cannot remove all the contaminated skin. Where the skin is thus affected, generally the progress of the disease is very rapid, and the patient dies in a short time, from effusion of serum into the chest. But the skin is often contaminated in another manner. It is thickened and brawny; the pores seem enlarged, as if you were looking at them through a magnifying glass, and you cannot pinch it up between your fingers as you can healthy skin. This is a very bad form of the disease. I have known the operation performed in two or three such cases, and the disease has always returned in the cicatrix directly, and the operation has appeared to hasten rather than to retard the fatal result. It does not matter how small an extent of skin appears to be thus contaminated; if any portion of it be in that state the seeds of disease are in the skin in the neighbourhood, and the knife divides what is apparently healthy, but what is not healthy in reality.

One effect of a scirrhus tumor of the breast, in a great number of cases, is to cause a contraction of the lactiferous tubes which pass from different parts of the head to the nipple; and this contraction of the lactiferous tubes causes a drawing in or retraction of the nipple. This retraction of the nipple, I believe, is to be regarded as very unfavourable to the ultimate success of an operation; for when the nipple is retracted the disease seems always to have extended to the skin in the neighbourhood, and if you examine it very carefully you will generally find manifest indications of disease in it.

Then, in many cases of scirrhus tumors of the breast, the skin is drawn in over the tumor, so as to produce the appearance of a dimple in it. Where this dimple in the skin exists you may be almost sure that there is a scirrhus tumor in the breast beneath it, and on examination you will feel it with the finger. I believe this dimple of the skin over the tumor to form a very great objection to the operation, so that

there is little or no chance of a permanent cure. But, on what does the appearance of the skin depend? I have carefully dissected the parts in a case of this kind, and I will tell you how it is produced. There is a small elongation of the disease passing up from the tumor through the adcps into the skin, a sort of scirrhus filament, half an inch, or a third of an inch, or a quarter of an inch in length. In fact, the dimple indicates that the disease is not confined to the breast, but that the skin is already contaminated.

Then, as the disease goes on, it contaminates the glands in the axilla. The glands in the axilla, if the breast be inflamed, may be inflamed and enlarged, as glands may be inflamed and enlarged from a boil or other inflammation in the neighbourhood. But when there are indurated glands of the axilla, independent of inflammation, you may be sure that there is the same disease in these that there is in the breast, that the axillary glands are contaminated, and that there is no ultimate cure to be expected from an operation.

You may say, "But remove the diseased glands from the axilla." I have done this, and seen it done, and I will tell you what invariably happens. Perhaps you have discovered only one enlarged gland in the axilla; you have determined to remove it, and when you have got into the axilla, you find other large glands contaminated in the same manner, though of too small a size to have been perceptible through the skin before the incision was made.

I need hardly tell you that if the scirrhus tumor adhere to the parts below—to the pectoral muscle and to the ribs, or if the skin be ulcerated, there is no chance of a permanent cure from the operation.

You will find patients sometimes, who, while they have a scirrhus tumor in the breast, have indications of the same disease, or some other form of malignant disease, in other organs. One patient may have signs of malignant disease of the liver; another, of the lungs; another, of the uterus. Of course, if there be any suspicion of the same mischief going on in internal organs, you will know that no permanent cure is to be expected from the removal of the diseased breast.

These circumstances, then, are sufficient to forbid an operation with a view to an ultimate cure; but you must also take into account the state of the patient, her age and condition in other respects: for instance, if an old woman has a scirrhus breast in a quiet state, you would never think of amputating it, because she may die first. The disease may outlast her.

Now, having taken away these cases, you will find in practice that there are very few

left in which you will think right to offer an operation, as affording a chance of permanent cure. What are the cases, then, in which the removal of the breast is proper? Where the skin is perfectly sound; where the nipple is not retracted; where there is no dimple in the skin over the tumor; where there is no diseased gland in the axilla; where there is no sign of internal mischief; where there is no adhesion of the breast to the parts below; and where the patient is not very much advanced in life: in a case where this fortunate combination of circumstances exists, I should say that there is a reasonable chance of an operation making a cure.

Still, I do not mean to say that in *all* these cases there will be a permanent cure,—far from it; but there will be, in *some* instances. The chances of it in such a case as I have described may be sufficient to warrant you in recommending the patient to submit to the operation; and I have the satisfaction of knowing several persons on whom I have performed the operation under these circumstances, who are now alive and well, and who otherwise would certainly have been dead long ago. So long since as 1832, I removed a breast affected with a scirrhus tumor, and the lady is still alive and well—at least she was so last year. Since the operation she has married and had children. Last year I was called to see a lady on account of another complaint, on whom I performed the operation as long ago as 1830, and there she was, still alive and well.

But besides such cases as I last described, there are others in which the operation for a scirrhus tumor connected with the breast may be performed with a still better prospect of success. A hard tumor sometimes forms on the surface of the breast, which feels like scirrhus, and on cutting into it, it looks like it; so that I can give the disease no other name. It appears to be unconnected with the breast; but when you remove it, you find that it is attached to the surface of the gland, just at one narrow corner. I have removed three tumors of this kind, leaving the breast uncut except where I separated the tumor from it; and in each of these three cases the patient was alive and well a considerable time afterwards. Indeed, I do not know that in any one of them there has been a return of the disease.

Again, a scirrhus tumor may occur in the nipple; and I believe that this may properly be distinguished from a scirrhus tumor of the breast itself, and that there is a greater chance of a permanent cure from an operation where the disease originates in the nipple, than where it originates in the breast. There was a lady who had such a tumor of the nipple. She consulted several surgeons

about it; and as the disease was in a quiet state, it was recommended that it should be let alone. After some time she came to London, and was under the care of the late Mr. Rose, who was a surgeon of this hospital; and I saw her with him. The tumor was still confined to the nipple, and had been going on for some years without coming to any harm; but it was now making progress. We agreed that it should be removed. Mr. Rose removed the breast, which appeared sound, the nipple alone being diseased. She recovered, and was alive and well many years afterwards. A lady consulted me concerning a scirrhus tumor of the nipple: at least I call it scirrhus, for it presented all the characters of that disease. It was as hard as scirrhus, and it had ulcerated. The breast itself seemed to be sound. She was a stout elderly lady, with an enormous breast, and a great deal of adeps over it. The removal of the whole breast would have been a frightful operation, and it is more than probable that her constitution would not have borne it. She was suffering great pain from the disease. I applied chloride of zinc, and afterwards the caustic potassa, till I destroyed what appeared to be the whole of the disease of the nipple. This was three or four years ago. The wound healed, and the patient is alive and well at this moment. The two last orders of cases are, then, to be especially distinguished from those of which I have spoken formerly.

But here another question arises. Is there no other reason for performing the operation for the removal of a scirrhus tumor of the breast, than the hope of making a permanent cure? May it not be worth while to perform it sometimes to give the patient a respite—to relieve her from present suffering, or with a view to prolong life for a limited period? Undoubtedly it is; and I will mention to you some cases illustrative of this observation. There was a lady about 40 years of age, who had a scirrhus tumor of the breast, and there was a cluster of diseased glands in the axilla. When she came to me the skin over the tumor appeared to be on the point of ulceration, so that the disease was going on to great mischief. I said to her, I am afraid the operation will not make a permanent cure, and I cannot recommend it. She asked whether I had anything better to offer; and I could not say that I had. She went away, but in two or three weeks came again. She then said that she had consulted two or three other surgeons (whose names she mentioned), and found that they were all of the same opinion. But she added, "I now come to beg a favour; and that is, that in spite of these opinions you will remove the breast." I

asked what her reasons were, and she said, "I am in these circumstances: I have a daughter 18 years of age, an only child. I know that I shall not survive very long; but it is a great object to my daughter that I should live to be her friend and adviser for two years longer. It is for this reason, and this only, that I wish to take the chance of an operation." There was no withstanding such an appeal as this, and I removed the breast, but never thought of touching the glands in the axilla. There was no distinct return of the disease in the cicatrix, and the glands in the axilla did not greatly enlarge; but at the end of two years she was seized with symptoms of disease in the chest; there was an effusion of fluid into the pleurae, and she died. I may take this opportunity of mentioning, that this is the most common way in which scirrhus tumors terminate life. Little miliary scirrhus tubercles form in the lungs, and then there is an effusion of fluid into one or both of the pleurae. There was a lady who came to me with scirrhus tumor of the breast. It was small, and so also was the breast, and I should have recommended the operation, but that there were two or three hard and large glands in the axilla. I said to her, you have not much suffering, I cannot recommend an operation; let it alone. A year after she came to London again. The tumor had now ulcerated, the glands had much increased, the ulcer produced excessive suffering, so that she was miserable. I did not remove the tumor with the knife, but I applied the chloride of zinc, and destroyed it. The sore healed. Some seven or eight months afterwards there was a tubercle formed in the cicatrix, which ulcerated like the former one, and I destroyed it in the same manner. She was enabled to go on with great comfort, in fact suffering very little, except at the time when the chloride of zinc was applied. At last, after the lapse of a year and a half, disease was established in the lungs, effusion took place into the pleurae, and she died in consequence of it. There was a lady who had a large malignant tumor of the breast: it was not exactly scirrhus, but approaching to it in its character; and I did not think that an operation would lead to a permanent cure. By and bye she came to me again, and now the tumor was very much enlarged. The skin was ulcerated, and the ulcer was horribly painful, so that her life was truly miserable. I said, I am afraid you will not get a permanent cure; but, suffering as you are, it is worth while to have the breast removed in order to relieve your present misery. The breast was accordingly removed; it was of a very large size; there was a very broad wound, with a great deal of bleeding; but

she recovered, and continued well upwards of three years. She had then some abdominal disease, and a tumor was felt in the belly, which I conclude was of the same character as the one in the breast. When I last heard of her she was supposed to be dying, and I imagine that she is now dead; but she was relieved of great suffering, and lived three years longer than she would have lived if the operation had not been performed.

I may mention another case. A lady came to town with a large tumor in one breast. There was a fungus protruding, and in the centre of the fungus there was an opening, through which a probe could be passed to the bottom of the tumor. There was also an enlarged gland in the axilla. Sir Astley Cooper saw the patient with me, and as she was suffering a great deal from the ulcerated tumor, we agreed that she should have the breast removed, not expecting a permanent cure, but merely a relief from her present distress. The breast was removed, the wound healed, and she had no return of disease in the breast; but a year afterwards her physician in the country wrote to me, saying that she had symptoms of some malignant disease going on in the chest. She died of effusion into the pleuræ. There was another lady with an ulcerated scirrhus tumor of the breast, which was so painful as to make her life miserable. I told her that I could not promise her a permanent cure; but as she was suffering miserably, she might as well have the tumor removed, nevertheless. She did so, and she lived in comfort for many months.

There may be, then, cases in which you are justified in performing the operation for the removal of a scirrhus tumor of the breast, not in the expectation of a permanent cure, but to obtain a respite for the patient and relief from present suffering. But here you must use some discrimination; for, if the skin be actually diseased, I cannot advise you to have recourse to an operation; the disease returning in the cicatrix so soon, that the patient will get not even a respite from it.

There is still another circumstance to be taken into the account when you come to give an opinion as to the expediency or inexpediency of an operation. Is there any danger in the operation itself? It is commonly said that this is not a dangerous operation; but I can appeal to the experience of all surgeons who have had much to do with it, whether they have not known persons die from it, and whether it be always free from danger? I know that it is not. I have myself lost patients after the operation, and every surgeon has had the same misfortune. Here I think that *something* depends upon the mode in which you per-

form the operation, and manage the patient before and afterwards; while a great deal depends upon circumstances not under your control. First, you should take care that there is as little hæmorrhage as possible at the time of the operation. Never believe those who stand by at any operation, and say, "the patient has lost no more blood than will do him good." Hæmorrhage during any operation is a great evil, and is one of the chief causes of failure: not that the patient dies directly of hæmorrhage, but indirectly. It lays the foundation of erysipelatous and of venous inflammation, and other mischief, some time afterwards. Then take care not to keep the patient very low before the operation. What used to be termed preparing for an operation by low diet is always wrong. The patient need not be stuffed and crammed before an operation, and she should have her bowels emptied; but as to repeated purging and very low diet, that is not right either before an operation or after it. An operation is a shock to the system, making a great demand upon the vital powers; and if you take away whatever stimulus and food the patient is accustomed to, the constitution probably will not bear it. So far, I say, the success of the operation is, to a certain extent, under your control; but then there are circumstances that are unfavourable, but which you cannot influence. For instance, in a large fat woman with an enormous breast the operation is frightful. There is an immense wound, and there will probably be great hæmorrhage in spite of all your care. An old woman will not stand the operation like a person less advanced in life. You are to look upon an operation, especially if there be a large incision, in an elderly person, as always attended with a certain degree of danger; and so it is when the patient is of a delicate and fragile constitution. For example, those women whom you meet with frequently in private practice with an hysterical nervous system, a small pulse, and cold hands and feet, are always unfavourable subjects for operations, especially for those that are attended with even a moderate loss of blood. In such women as these you are to avoid an operation if possible. But where the breast is small, where the patient is otherwise healthy, and not much advanced in life, and where you do not starve the patient either before the operation or after it, and are also careful that there shall be as little loss of blood as possible, there the danger of the operation is comparatively trifling.

I have spoken of the operation for the removal of scirrhus tumors of the breast; but the breast is liable to other malignant diseases, and the observations which I have just made apply to these cases as well as to

the others. I think, however, that where the malignant disease of the breast has the form of fungus hæmatodes, the chance of ultimate success is even less than where the disease has the form of scirrhus. Fungus hæmatodes is a worse form of malignant disease than scirrhus; and in most of the cases of it which I have seen in the breast, where the tumor has been removed by operation, the patient has always died in a short time afterwards of disease of the lungs and effusion into the pleuræ. But, after all, I believe that these are essentially the same disease, whether assuming the form of scirrhus, or fungus hæmatodes, or pancreatic sarcoma. Whatever may be the names given to them by pathologists, you may be assured that malignant diseases are all nearly related to each other, and that the remarks which I have made respecting the one are applicable to the rest.

I will mention some cases to illustrate this last observation, which I think it is of importance in practice that you should not forget. There was a woman who had a scirrhus tumor of the breast; there was that brawny condition of the skin which I have already described, as indicating a very bad form of the disease. The whole of the skin was converted into a scirrhus tumor, so that the tumor of the breast was scarcely to be distinguished under it. She had also some disease of the liver, and there was a discharge from the uterus. She died, and on examining the breast there was a scirrhus tumor well marked; but in the liver there was a tumor having well-marked characters of fungus hæmatodes or medullary disease; and in the uterus there was an excrescence of that kind which the late Dr. John Clarke described as cauliflower excrescence of the uterus, and which he regarded as an incurable malignant disease of that organ. So that these three diseases, all malignant, and to which different names have been given by pathologists, were all associated in the same individual. The preparations showing them are in the museum. Here the different diseases all coexisted, but I have seen them occur in succession, and I will mention a case in point. When I was a young man, I went with Sir Everard Home to perform a private operation. It was in the case of a lady from the country, who had a tumor apparently in the abdominal muscles. Sir Everard removed the tumor, and when we came home and examined it we found that a portion of peritoneum adhered to it, and that it was a plain case of scirrhus tumor. The wound healed very well, and the lady went out of town. In the course of a little time, however, she again came to London, with another tumor formed in the cicatrix. She

again put herself under Sir Everard Home. The tumor was larger than the one he originally removed, but he removed it as he did the former one. It had no longer the characteristic structure of scirrhus, and I can only describe it by saying that it was like the fibrine of the blood, without colour; laminated; something like the buffy surface of a coagulum of blood drawn during inflammation, and very slightly organized. The wound healed, but by and bye a third tumor formed in the cicatrix, and she again came to London. It seemed not worth while to remove the tumor a third time. It increased in size, and occupied a great part of the belly. She died, and it fell to my lot to examine the body. The tumor was entirely different in appearance from either of those that had been removed. It was a regular brain-like or medullary mass, or a tumor of fungus hæmatodes. Hence, in the one case three different kinds of malignant disease existed in the same individual at the same time, and in the other they showed themselves in succession. You may sometimes remove a tumor from the breast, in one part of which you have one structure, and in another a different structure.

There is a circumstance which I ought to have mentioned in an earlier part of the lecture, but which I accidentally omitted, and which ought always to be taken into account whenever you are in doubt as to the expediency of the operation. It is very true that a scirrhus tumor of the breast will generally terminate the patient's life, if left to itself, in three or four years, but very often it lasts much longer. I remember a lady of fashion who had a scirrhus disease of the breast; who lived in the world, and nobody knew anything about it for several years, I believe ten or fifteen. I remember another lady who had a scirrhus tumor of the breast twenty-five years, and she died at last, not from the disease of the breast, but from effusion into the cavity of the chest. If you are doubting about the expediency of an operation, and the disease be in an indolent state, the recollection of such cases as these, where the patient has lived with a scirrhus tumor of the breast unaltered for many years, should be sufficient to incline you to reject it. The chance of a patient living long with such a disease is not sufficient to make you throw away the chance of an operation, where it is likely to be attended with advantage, but is sufficient to make you decline the operation where other circumstances would lead you to doubt its propriety.

THE COLLEGE CHARTER.

To the Editor of the Medical Gazette.

SIR,

I FELT much surprised at the conclusion you arrived at after your recent examination of the new charter of the College of Surgeons; viz. that it cannot be doubted for a moment that it is a prodigious step in the way of improvement.

I should have thought that even the not unfriendly analysis of its provisions exhibited in your pages, must have led to a very different conviction. A more inefficient, complex, contradictory, and inoperable plan for satisfying the wishes of the profession, could scarcely, I think, be devised. Throughout it betrays an unwilling submission to concessions which had become inevitable, and a disposition to hamper them with restrictions and regulations which may render them nugatory. Had the Council of the College met the members of its body in a frank and cordial spirit, and published the heads of any plan they might have been able to contrive, such plan might, by the aid of discussion through the press, the employment of deputations from those interested in the matter, &c. &c. have become, perhaps, satisfactorily matured and practically useful; whereas the present measure, carefully shrouded from observation until expostulation and amendment had become too late, is pronounced, even by its well-wishers, to be but a bungling piece of business at the best.

There can be no doubt, I think, that the great body of the members of the College must be, if this new fellowship is to be worth having at all, degraded by the elevation of a fraction of their number to a higher rank, independently of superiority of qualifications; that is to say, such superiority has not been made the test, and cannot be alleged of a great number of those selected. What good object is to be attained by the creation of this body of electors, as Mr. Guthrie, with his usual directness of expression, terms them, I know not. They are too numerous for the same dispatch of business and concentrativeness of action which characterise smaller bodies, while they are not numerous enough to prevent the possibility of sinister or family influences operating among them, and certainly not enough to be entitled to be considered as expressing the voice of the profession in reference to candidates submitted to them.

But why this system of indirect expression at all? It can scarcely be pretended that the same arguments which are used in reference to universal suffrage in the political world will apply to it in medical affairs.

The profession is not a mob, but consists of a large number of persons who are, or should have been before the diploma was granted them, educated gentlemen, and who are fully alive to the professional merits of their brethren, and upon all occasions willing to testify to the same, and to whom, I contend, such opportunity of testifying can alone be justly assigned.

I cannot agree with those who approve of the selection of Fellows which has been made. It would have been hard indeed, with the whole profession to choose from, if some or many well-known men had escaped cognizance; but we have the right to complain of the almost utter absence of the names of general practitioners of eminence. It is replied—a leading rule laid down for the selection was the inclusion of every surgeon and assistant-surgeon of a recognised hospital, and every lecturer or demonstrator of surgery and anatomy at every school; and that this necessarily swallowed up a large portion of the 300. Of course it did, and any such basis of selection is very unsatisfactory, and should never have been laid down; for every one knows that the election to surgeoncies and lectureships is too frequently effected through family and other influences, and is often but little proof of excellence. And although the most eminent names of our own and former times have and do grace these offices, yet others are filled by men of a very common-place description, in no wise entitled to elevation at the expense of their brethren. The test you lay down yourself, Sir, is a better one, although I am at a loss to know how you have discovered its application, or what assurance we have in future for its realization. Your words are, “The Fellowship is an honour properly held out by the Queen as a reward to those who have *distinguished themselves* either as authors, or as practitioners, or as discoverers, or as men of general science, or of high character and reputation, or long standing in the profession.”

Whether some general practitioners might not have been selected in accordance with these principles of selection, I need not ask; but I may observe that even if the proportion of these had been much greater, I do not think the profession either would or ought to rest satisfied with such a measure as this new charter, and that nothing should content them but the admission of a certain proportion of leading members employed in general practice into the Council of the College itself. I can see no objection of the slightest weight to this arrangement, while it would assuredly assuage much of the heart-burning ill-will now prevailing. The objection on the score of pharmacy is idle, for every one knows that a general practitioner of any eminence is never engaged in

the actual practice of pharmacy, which is entirely managed by his assistants and apprentices; while an acquaintance with its principles must surely be advantageous to any one engaged in the art of prescribing, and would, I feel sure, be of great utility to some of our present surgeons, would they condescend to acquire it. This I can hardly expect, since they require not only that a member of their Council shall not be engaged in the practice, but shall be also in condition to shew that he has sufficiently purified himself therefrom by a five years' quarantine. The prohibition against midwifery you have animadverted upon; and I can only express my utter astonishment that a body so enlightened as the Council, containing men who have so eloquently advocated the indivisibility of the science of medicine, and others who have practised all its branches, could consent to promulgate so foolish a decree, and that with the experience of the benefit accruing to the College of Physicians from the repeal of such an enactment. If the surgeons of the present day are determined to restrict their honours to the operative branch of medicine, they are certainly less particular as regards their own practice, for I am, at least, unable to define the case they would refuse their attentions to.

I believe, then, Sir, the interests of the profession would be best consulted if the Council of the College consisted of a much larger number of persons, say 50 or 100, general and provincial practitioners, in certain proportions, being eligible; the ordinary business being performed by committees residing in London, as at present for the library, museum, &c.; and that each member of the College should have the power of voting at every vacancy.

If, however, an order of Fellows is to be created, it should be accessible, as suggested by Mr. Guthrie, to any one of the profession who chose to undergo the additional examination, and pay an additional fee, for I cannot see the policy or justice of not demanding a fee for the Fellowship, if it is to be retained for the Membership, as it undoubtedly should be.—I am, sir,

Your obedient servant,

JOHN CHATTO.

Great Coram Street, Jan. 8, 1844.

TAUNTON AND SOMERSET HOSPITAL.

To the Editor of the Medical Gazette.

SIR,

I AM sorry that my observations on the terms proposed for a surgeon to the Taunton and Somerset Hospital should have offended

Mr. Higgins (who stands boldly forward in defence of the office which he holds), or any member of the election committee. I had no intention of impugning the limited circumstances of any medical practitioner, nor of discouraging the zeal of any young surgeon, who, instigated by a laudable anxiety to improve his professional attainments, accepts an office calculated to fulfil his object. My indignation was especially excited by those terms contained in the advertisement for a surgeon which, in my opinion, derogated from the dignity of a gentleman embarked in a liberal profession, and which seemed analogous to those of an upper servant in a gentleman's family. To prevent any farther misinterpretation, my allusion was not so much to the salary of £50 per annum, as to the *classing the surgeon with the matron*, by placing him at her table, *restricting him from practising out of the hospital*, and the offer to *defray the expenses of his landress*! Now, sir, had the committee, though they limited the salary to an annuity of £50, given him the liberty of private practice, not inconsistent with his hospital duty, and allowed him the privilege of dining in his own apartments, I should have started no objection to an office so desirable; but though the matron may be, and no doubt is, a highly respectable person, the office which she holds being unquestionably menial, should surely exempt a surgeon from the *condition* of commensality; and if the protection from the expense of his washing bills were considered an object for the probable candidate, a further compensation to that end might have been privately awarded, without offending his delicacy by the public offer of such indemnification. The rector of a parish advertises for a curate; and though the salary which is offered may not exceed £50, the curate is not required to sit at table with the housekeeper, nor is he offended by the offer of the gratuitous use of the family wash-tub. The poor ensign of a regiment, or the midshipman on board a frigate, mess with their brother and superior officers. So that, in the other liberal professions, though the salary be humble, or the pay scanty, their station in society is untarnished. I will not, however, trespass at greater length on the pages of your Gazette. I have merely made these observations in defence of a profession of which I am a member—a profession which I lament to say is not properly estimated or respected—and from a repugnance to see any of my colleagues insulted or underrated.

“*Ἱητρος γὰρ ἀνὴρ πολλῶν ἀνταξίος ἄλλων.*”

I am, sir,

Your obedient servant,

J. C. BADELEY, M.D. Cantab.

Guy Harlings, Chelmsford,

Jan. 25, 1844.

COLLEGE OF SURGEONS.

To the Editor of the Medical Gazette.

SIR,

RESIDING more than a hundred miles from London, and being ignorant of the principle which guided the Council of the College of Surgeons in their recent appointment of Fellows, allow me to suggest, in answer to Mr. Edwin Lee's complaint at being left out of the number, whether, notwithstanding Mr. Lee's numerous publications, the favour he has shewn to the most absurd of the pretensions of *Mesmerism*, in his late "Report on Clairvoyance," may not have influenced the Council in omitting his name?

Were the suffrages of the new Fellows to be taken as to his admission amongst them, I suspect the reason I have mentioned would decide nine out of every ten against his claim.—I am, sir,

Your obedient servant,
ONE OF THE FELLOWS.*

COLLEGE OF SURGEONS.

To the Editor of the Medical Gazette.

SIR,

As you have honoured a letter of mine by placing it in your pages, perhaps you will allow me to offer, on the same subject, a suggestion to the Council of the Royal College of Surgeons of England. I would put it as questions for consideration. Is it not desirable, in various points of view, that the new Fellows which are to be elected before the 14th of September, should know of their election so soon as it has taken place? Is it not desirable that the election should be carried on in chronological order, so that those who are passed over may know it before the expiration of the time allowed, in order that any such who feel themselves competent to undergo the examination for Fellows may without delay take that position in the profession for which they believe themselves duly qualified? There may be many modest yet meritorious members to whom it would be very painful to find on the 14th of September that they are not Fellows of the College, and perhaps some of them far superior to many on whom the honour has been conferred.—I am, sir,

Your obedient servant,
A TWENTY-EIGHT YEARS MEMBER.

January 29, 1844.

* A very distinguished provincial surgeon.
ED. GAZ.

EXTRACTS

FROM THE

Report on the Progress of Anatomy and Physiology in the year 1842-43, by JAMES PAGET, Lecturer on Anatomy and Physiology at St. Bartholomew's Hospital.

Blood.—Concerning the *general constitution* of the blood, MM. Andral and Gavarret, continuing with M. Delafond the observations already made on human blood, have examined that of many domestic animals, and have drawn these conclusions: 1. In the species examined, the principal constituents of the blood are the same, but the proportions of each vary. 2. The highest natural average quantity of fibrin is in the herbivora, the lowest in the carnivora: the energy of constitution has no constant influence on the increase of the proportion of fibrin. 3. Of the corpuscles the highest average proportions are found in the carnivora, the lowest in the herbivora; and in the same species there is always an increase proportionate to the energy of the constitution; and in sheep, to the improvement of the breed. 4. During the first day after birth the fibrin is in very small quantity; the corpuscles comparatively abundant. 5. During the last periods of gestation, both fibrine and corpuscles fall below the healthy proportion; after parturition they increase to more than that proportion. 6. The fibrin (in the domestic animals as well as in man) is always increased in the inflammatory state: the corpuscles are never directly influenced in it. 7. The water of the blood has its lowest average in the carnivora, its highest in the herbivora. 8. Dropsy does not supervene on alteration of the blood, unless from diminution of albumen; excess of water or decrease of corpuscles will not produce it.

Rigor Mortis.—An ingenious paper has been published by Ernst Bruecker, to prove that the rigor mortis is due to the coagulation of the fibrin which is effused from the blood-vessels in the liquor sanguinis for the nutrition of the tissues, (especially of the muscles,) but which at the time of death has not yet been assimilated. The paper is chiefly important for the numerous analogies which it points out between the coagulation and subsequent changes of the fibrin and the contraction of the muscles; analogies of which Mr. Hunter had already illustrated many, and some of the most important. But the explanation of the rigor mortis is rendered improbable by the observations of Mr. Bowman, which I can fully confirm, and which prove that the muscle is rigid, because its fibres, or parts of them, are contracted, and contracted in the same manner as during

life. And some examinations which I have made of the rigor mortis in the involuntary muscles, afford equally strong evidence of its being due in them also to the muscular contraction. I believe that *all involuntary muscles* pass into the continued and fixed contraction of the rigor mortis as soon as they cease to be irritable, and to contract under ordinary stimuli. This may be seen distinctly in many arteries, as well as in the digestive canal and urinary bladder; but the best examples are presented in the hearts of recently slain animals, or of men examined soon after apparent death. As soon as they cease to be irritable, the walls of all their cavities, previously flaccid, gradually become firm and hard, draw in towards the base of the heart, and reduce or completely close the cavities. The heart thus rigid has almost exactly the form and other external characters of the heart when actively contracted during life. It is evident that this form, produced as it is by a drawing up towards certain fixed points of attachment of the muscular fibres, could not be acquired by the mere coagulation of either blood or liquor sanguinis within the tissue of the heart; and the only difficulty in believing that the rigidity of the heart and other muscles is due to a contraction comparable with that which occurs during more active life, must be from the seeming improbability that any tissue should maintain a vital contraction so long after apparent death as during the continuance of the rigor mortis. This difficulty, however, which would in any circumstances be more apparent than real, is almost removed by the facts already quoted from Remak.

Exhalation of Carbonic acid.—MM. Andral and Gavarret state the following as the results of experiments made in sixty-two persons (thirty-six males and twenty-six females), to determine the quantity of carbonic acid exhaled in breathing: 1. At all ages beyond eight years the exhalation is greater in males than in females. 2. In males it regularly increases in quantity from eight to thirty years of age; from thirty to forty it is stationary or diminishes a little; from forty to fifty the diminution is greater; and from fifty to extreme age it goes on diminishing till it scarcely exceeds the quantity at ten years. 3. The quantity of carbon exhaled in the form of carbonic acid in one hour by males of different ages is as follows;—at eight years, 77.5 grains; at fifteen, 135 grains; at twenty, 176.7 grains; between thirty and forty, 189 grains; between forty and sixty, 156 grains; between sixty and eighty, 142.5 grains; and in a man of 102 it was only 91.5 grains. 4. In females the same proportionate increase goes on to the time of puberty, when the quantity abruptly ceases to increase, and remains stationary so long as they continue to menstruate.

When, however, menstruation has ceased, the exhalation of carbonic acid begins again to augment; and, then again, in advancing years, decreases as it does in men. Thus before puberty the quantity of carbon exhaled by girls in an hour is ninety-nine grains; and so it continues while the habit of menstruation continues; afterwards, from thirty-eight to forty-nine years of age, it increases to 130 grains; from fifty to sixty again falls to 113 grains; from sixty to eighty is reduced to 105 grains; and in a woman of eighty-two, was only ninety-three grains. 5. In amenorrhea the exhalation is always increased. 6. In pregnancy the exhalation is equal to that which is natural soon after the cessation of menstruation. 6. *Ceteris paribus*, the more robust a person is the more carbonic acid is exhaled; but the differences are not great. 7. The maximum of exhalation was in a strong man of twenty-six, who in an hour exhaled carbonic acid containing 218.5 grains of carbon; the proportionate minimum in a weak man of forty-five, who exhaled in the same time only 139.5 grains. 8. The influences of the weights of persons, of the capacities of their chests, and of the extent of the respiratory movements, are not great.

Salivary secretion.—Dr. Budge has found that after extirpation of the parotid, submaxillary, and sublingual glands in a dog and a rabbit, the secretion of saliva continued; its characters remained the same, and no function was disturbed. [The experiments add probability to the opinion that the labial, buccal, palatine, and other glands which the experimenter left behind, are salivary glands.]

A case of a kind of metastasis of the salivary secretion is related by Dr. Roelants, and is interesting in its relation to the general physiology of secretion. A man, eighty-two years old, had an attack of bronchitis, with fever, followed by suppuration around and probably in one of the parotid glands. The abscess was opened, and two months after a large mass of chalk-like substance was discharged. The abscess soon healed, and he recovered his health; but now, whenever he masticates, saliva flows freely from the skin of the cheek and temple of the side formerly diseased. As soon as he begins to eat, the skin becomes very full of blood, and hot; and gradually drop after drop of clear fluid, with all the characters of saliva, collects on its surface, and runs down the cheek and neck, and continues to do so just as long as he continues eating. His health is not disturbed, and the saliva-secreting surface of the skin is natural in its texture.

Composition of the Bile.—Dr. Kemp, by careful elementary analysis of the bile of the ox, has corroborated Demarçay's opinion that it is essentially a true chemical com-

pound of an electro-negative body with soda. But he holds that this body is neither the *choleic acid* of Demarçay, since it is not precipitated from the soda by acetic acid, nor the *bilin* of Berzelius, because it is not precipitated from the soda by carbonic acid. He has therefore given it the name of *bilic acid*. It has a peculiar bitter-sweet taste, and in mass resembles a fine resin. It is soluble in every proportion in water. In a subsequent paper he has shown that a much greater difference than is usually imagined is effected in the bile while in the gall-bladder. Bile from the hepatic ducts of an ox was destitute of the bitter taste of cystic bile; its smell also was different. It chiefly consisted of two different electro-negative bodies, separable by alcohol, and each combined with soda.

Testicles.—Mr. Gulliver has confirmed R. Wagner's observation, that the general enlargement of the testicles which takes place as the period of procreation approaches is accompanied by enlargement of the individual seminal tubes. During winter he finds that the seminal tubes of birds are tolerably thick and strong; but at the season of procreation semen accumulates in them, and their coats are so distended and attenuated that they are very easily ruptured. The same thinning and enlargement of the tubules occurs in the development of the human testicles at puberty.

An interesting case, proving the sympathy of the vital organs with the testicles, is recorded by Dr. Schlesier. A healthy man engaged in a fray in the dark, was suddenly heard to shriek out: he fell in convulsions, and died in five minutes. On examination the only injury found was the rupture of both the spermatic arteries and veins at the internal rings, produced by the scrotum and testicles having been seized and pulled down by one of those with whom the man was fighting.

Spermatozoa.—Facts of much importance in regard to the formation of spermatozoa are furnished by the cases first recorded by Mr. Liston and Mr. Lloyd, and since repeatedly observed, in which these bodies are found in the fluid of common hydrocele of the tunica vaginalis testis, and in encysted hydrocele.

Lactation.—M. Mandl confirms the view of Henle and others in regard to the perfect milk-corpuscles, proving the existence of an external membranous envelope by rubbing the corpuscles between glasses. The oil-globules are set free, and the torn membranes are unrolled and flattened.

M. Raciborski has examined the question of the influence of menstruation on the secretion of milk, and has found that it is unimportant. The only difference between the milk of nurses who do, and those who

do not menstruate, is that in the former the proportion of cream is rather less in the menstrual period than it is in themselves in the intervals, and than it is generally in non-menstruating nurses.—*British and Foreign Medical Review.*

STATISTICS IN MIDWIFERY.

BY DR. METCALE.

THE case where *one foot and one knee presented*, being soon converted into a footling presentation, was got along with as far as the head, without difficulty. Here it was arrested, and for a while resisted my utmost endeavours; but, with the fingers depressing the chin, and the exercise of no inconsiderable force, delivery was accomplished in season to preserve the life of the child.

The *breech presentations*, of which there were three, all did well. One of them was attended with the longest uterine contraction I ever witnessed. At its commencement, I was sitting below stairs in conversation with the husband, from whom I was summoned by one of the attendants. On entering the room, I found the patient in strong pain; and, on making an examination, I ascertained that the breech presented, and was rapidly passing through the superior strait of the pelvis. The uterine effort continued without the least intermission, until the delivery was wholly completed. Twenty-five minutes before this I was unable to make out the presentation. It was a fourth labour, and the whole process was accomplished in three hours. From its completion at 8 P.M. until 4 of the clock the next morning, the patient continued very faint; the syncope, at times, being quite alarming. There was a copious hæmorrhage for the first hour or two, but I attributed the faintness more to the rapidity of the labour, and the suddenness of the delivery, than to that circumstance, the patient being of a very full and plethoric habit. In all three of the cases no trouble was met with at the delivery of the head; with a finger in the mouth, and the chin depressed upon the breast, very little force was requisite to finish the labour.

In both cases where the *funis presented*, the child was dead some time before birth. One occurred in a case to which I was not called until some hours after the pulsation in the cord had ceased. The presentation was natural, the delivery was readily accomplished, and the child, which was a male, was found to be a very large one, weighing 11½ pounds. It was the fourteenth child. The other case has already been referred to as the face to the pubis presentation, and was a miscarriage in the eighth month. The cord was found prolapsed at the first ex-

amination, and I was unable to reduce it behind the presenting part after repeated trials. Dr. Smellie says, "when the cuticle is detached, or nearly so, from the body of a new-born infant, it is evidence that the child has been, *for some days*, dead." In this instance the umbilical arteries pulsated strongly for many hours after I was called, and continued to do so until within twelve hours of the birth of the child. The life of the child was also proved by the strong and sensible motions which could be plainly felt through the abdominal parietes; yet, when born, the cuticle was off in many places about the body, and one arm was entirely denuded.

The case of *presentation of the placenta* occurred in an abortion at five months. On coming at the residence of the patient, which was five miles distant, I was told that she had been flooding for some time, and had become very faint. The attendants were very much alarmed, and urged an immediate examination. On complying with their solicitations I found the vagina filled up with what I supposed to be a coagulum; but, a pain occurring at the moment, it was expelled, and was found to be the placenta, completely separated from the fœtus by the rupture of the umbilical cord. A succeeding examination brought on another uterine contraction, and the fœtus was soon afterwards expelled. Pressure upon the abdomen, together with the administration of diffusible stimuli, and large doses of acetate of lead and opium, arrested the hæmorrhage. The patient continued extremely feeble for some days, and ultimately recovered after a tedious and protracted convalescence. This was the fourth time that abortion had occurred to the patient, having, in no one of her former pregnancies, arrived at the sixth month. She has since been delivered of a healthy child at the full time.—*American Journal of the Medical Sciences.*

INFLUENCE OF MENSTRUATION ON THE SECRETION OF MILK.

M. RACIBORSKI, in a memoir lately read to the Academy of Medicine, has sought to establish, by a collection of facts, the influence of menstruation on the general health of nurses and on the secretion of milk. The medical profession has been very much divided on this point; for whilst some think that menstruation does not injure the quality of the milk, and, of course, ought not to be regarded as a reason for a woman ceasing to nurse, others consider the occurrence of menstruation as hurtful to the quality of the milk, and will not permit a woman to nurse in whom the menses are flowing.

M. Raciborski examined with care the milk of seven nurses both during the intervals between menstruation and whilst that flux flowed. He examined its general appearance, its chemical reaction, its density, the relative amount of cream, the microscopic appearance of the globules, their number, diameter, and mode of arrangement, and compared these with the milk of an equal number of nurses who had not menstruated; and, lastly, he inquired minutely into the state of health of the children who sucked the nurses who menstruated. The general conclusions were:

1. Contrary to what has been lately averred, the milk of nurses who menstruate whilst nursing does not appear to differ in its physical quality, its chemical reactions, or microscopic appearance, from the milk of nurses who have not menstruated.

2. The only peculiarity which seems to present itself is, that, in most cases, it is less rich in cream during the continuance of the menstrual evacuation than during the intervals between that flux; and it is to this peculiarity that the bluish aspect of the milk, observed in some cases, ought to be attributed.

3. In respect of the influence of the mother's milk on the infant during menstruation, its supposed inconveniences have been much exaggerated; and a nurse ought never, in any case, to be rejected simply because she continues to menstruate.—*Journ. de Pharmacie*; and *Edin. Med. Journ.*

CLEANING GLASSES PREVIOUS TO MOUNTING OBJECTS.

It is highly essential, before putting any cement or liquid on glass which is intended to bear an object, that it should be perfectly free from "greasiness," and water should flow uniformly over the surface. To effect this, it is usual to have recourse to alcohol, alkaline solutions, or sulphuric acid; but recently the Rev. J. B. Reade has discovered that infusion of nut-galls (which is a solution of tannic acid) answers the purpose equal if not better than any of the preceding.—*London Physiological Journal.*

KING'S COLLEGE HOSPITAL.

To the Editor of the Medical Gazette.

SIR,

My attention has been called to a letter headed "London and Provincial Hospitals," which appeared in your journal on the 19th of January. As the insinuation contained in that letter has remained uncontradicted in either of the two numbers of the *MEDICAL GAZETTE* which have since been published, both you and your correspondent must have overlooked a letter which appeared in

the Morning Post on the 6th of January, and a copy of which I therefore now subjoin, with a request that you will, as a matter of justice, insert it in the forthcoming number of your hebdomadal.

Your obedient servant,

RICHARD PARTRIDGE,
Dean of the Medical Department,
King's College.

Feb. 7, 1844.

"To the Editor of the Morning Post.

SIR,

WITH reference to a paragraph appearing in the Morning Post of yesterday, and headed 'King's College Hospital—Town and Country Practice,' I have to request that you will give equal publicity to the statement, that it was inserted without the knowledge or sanction of any of the authorities of that institution, and much to the annoyance of the gentlemen whose names have been thus brought before the public. I have since ascertained that the paragraph owed its origin to a feeling of gratitude on the part of a person who had been a patient in the hospital.—I am, sir,

Your obedient servant,

E. C. STEVENS, Secretary.

King's College Hospital,
Jan. 6, 1844."

SIR BENJAMIN BRODIE'S LECTURES.

As our readers well know, we have for several years reported the Lectures which Sir Benjamin Brodie gives at St. George's Hospital. This season the *Lancet* has likewise done so, and last week, *by missing a Lecture*, and going on to the next in order, it has contrived to get one a-head of us. Nothing would be easier than for us to recover our ground by giving two; but this would interfere with those arrangements by which a correct version of those valuable discourses is secured to the readers of this journal.

ON
DIFFERENT FORMS OF GRANULAR
DISEASE OF THE KIDNEY.

By J. D. HEATON, M.D.

[Continued from page 564.]

(For the London Medical Gazette.)

ROBERT YOUNGER, aged 48, admitted under Dr. Williams. A tall man, of spare habit and melancholic temperament. His habits have been temperate; he has lived in a healthy situation, and followed the occupation of a porter, but has been able to procure only scanty support, and insufficient clothing. He has long been a dyspeptic patient, suffering from pain at the stomach and bilious vomiting, which symptoms have latterly become more severe.

He began to be seriously worse than usual about six weeks ago, when the pain and oppression at the stomach after taking food became more severe, and were accompanied with a distressing cough, continuing for some time after his meals; also, he had severe attacks of palpitation, and shortness of breath, which were relieved for a time by taking a small dose of brandy. The bowels have been very irregular; he has observed nothing unusual as to the urine. About a fortnight ago his feet and ankles, and afterwards his legs, became œdematous; but the rest of the body was not affected.

At present he complains of pain under the margin of the ribs, extending across the body in front; most severe in the epigastrium and right hypochondrium. He has a large appetite, but almost any kind of food increases the pain; the tongue is pale, large and furrowed, covered with a thin white coat. The dull stroke-sound of the liver extends unusually low in the abdomen, reaching down to the umbilicus. The bowels are costive. In the chest the respiratory sounds are tolerably healthy, but there is

more vocal resonance under the right clavicle than under the left. There is extensive dullness of stroke-sound over the cardiac region, showing considerable hypertrophy of the heart; the impulse, however, is somewhat feeble, and the sounds indistinct, especially at the base; the action of the heart is irregular. He complains of shortness of breath, and occasional palpitation. Pulse 66, rather full and strong, but intermitting. The feet and legs are œdematous, but there is no ascites, nor œdema of other parts. The surface moderately warm and perspirable. He has occasionally a dull pain in the loins, but there is no tenderness. The urine is pale, clear, and copious, slightly acid; its specific gravity is 1010; nitric acid, or the application of heat, throws down a considerable precipitate of albumen.

℞ Hydrarg. c. Creta; Pulveris Antimonialis, aa. gr. iij. M. fiat pulvis omni nocte sumendus.

℞ Haust. Sennæ; Infus. Quassiae, aa. ℥ss. M. fiat haustus omni mane sumendus. Middle diet.

June 3d.—He has been freely purged by the medicines. Has less pain in the epigastrium, but there is still much tenderness. Most of the symptoms continue as last reported. He complains of much debility.

Sumat. dimidium tantum pulveris et haustus.

5th.—No great change in the symptoms. His chief complaint is of great debility, and the pain at the epigastrium. The pulse is very irregular; the urine presents the same appearances as before.

℞ Infus. Calumbæ; Aquæ Menth. aa. ℥ss.; Sp. Ætheris Nit. ℥ss; Tr. Cantharidis, ℥℥x. M. ft. haust. ter die sum. Full diet.

On the 7th, as he was a good deal purged by the senna draught, he was ordered to discontinue this. On the 10th he commenced

taking purgative doses of bitartrate of potash every other morning; the pain at the epigastrium, the dyspnoea, and prostration of strength, were not much relieved, and the state of the urine not changed. To these symptoms, on the 11th, was first added vomiting, with violent retching, even when nothing was contained in the stomach; appetite quite lost; pulse more feeble, and very irregular. As the bowels were not acted on by the bitartrate of potash, he was ordered a common purgative draught, which acted, though not very sufficiently. The symptoms continued unrelieved, the sickness and vomiting being unabated. The matter discharged was a thin glairy fluid, not bitter nor sour. To relieve these symptoms, a draught with hydrocyanic acid, and afterwards a full dose of calomel, were ordered.

On the 14th, the report is, that the sickness and vomiting are considerably relieved, though not altogether removed. A little food was retained this day, though every thing taken for the last two or three days previously has been immediately rejected. The pain and tenderness at the stomach, with a sensation of tenderness, continue. He feels a weight in the head, with giddiness. Epistaxis has occurred two or three times during the last few days. He was ordered to repeat the dose of calomel; and the next morning took a purgative draught, which operated freely: the sickness was much relieved. From this time he began to suffer much from a sensation of oppression and giddiness in the head, with distressing sleeplessness, but with a great desire for sleep; also much dyspnoea, which could not be accounted for by anything observed in the physical examination of the chest. It was thought the dyspnoea might be asthmatic, and half-grain doses of extract of stramonium were given, with the view of relieving the supposed spasm of the air-tubes. This produced some relief, and for a day or two he appeared more comfortable than usual, though still much oppressed with drowsiness, which he could not relieve by sleep. At this time the pulse was about 80, and pretty regular when sitting up; but it was observed that, when the patient lay down, every other pulse became almost imperceptible, so that the number of pulsations seemed reduced one-half. The dyspnoea was most oppressive when lying down; so much so that sometimes he was quite unable to retain the recumbent posture. The dropsy was not reduced, and the urine retained its former characters; but he now was quite free from pain in the loins.

On the 20th, the following change was made in the medicines, with the view of endeavouring to increase the natural secretions of the kidney:—

Osmic in decumant.

R Spir. Junip. Co. ℥ss.; Sp. Armoracæ Co. ℥xx.; Tr. Digitalis, ℥x.; Decoct. Senege, ℥i. M. ft. haust. ter die sum.

The continued sleeplessness seemed to require an opiate, which procured him a tolerable night's rest, followed, however, the next day, by much disturbance of the stomach.

On the night of the 21st he awoke suddenly from sleep, and commenced talking in an incoherent delirious manner; in two hours he became collected; but this was followed by coldness of the surface and rigors, which were relieved by hot water bottles.

R Pulveris Antimonialis, gr. iij.; Ext. Belladonnæ, gr. ss. M. ft. pil. ter die sumenda.

These pills seemed to afford him a little temporary relief, but the symptoms from this time gradually became more aggravated. No change was produced by the last mixture in the character of the urine. The dyspnoea became more oppressive, so that he was immediately awoke from any slumber which could be induced, by the sensation of suffocation. It was always increased by the recumbent posture; but he was subject to paroxysmal aggravations, which were very distressing. He emaciated very rapidly; and this, with his constant suffering, gave the face a very ghastly appearance. He was much oppressed with constant nausea and anorexia, and had a very troublesome hollow cough, almost resembling the effort of retching, but without any expectoration.

The dose of cantharides in the mixture was increased, and laudanum added with the view of inducing some sleep; but all the symptoms gradually became aggravated. Creasote, calomel, and other remedies, were tried, to relieve the constant sickness, but with little success.

On the 29th the quantity of albumen in the urine became unusually great, so that the specific gravity was raised to 1013. The oedema of the feet appeared on the increase, but the dropsy was still confined to this part. The other symptoms were not relieved. An examination of the chest at this time discovered some obscure crepitation posteriorly at the base of the lungs, and distinct dulness of stroke-sound under the right clavicle. The pulse at this time was quite regular, feeble, but hard; the sounds of the heart feeble, but regular, and without much morbid character. The bowels being costive, he was ordered again five grains of calomel, and a dose of castor oil; and quarter of a grain of morphia twice a day, to procure him some sleep.

This amount of morphia threw him into a constant doze; and though he desired it, as rendering him less uncomfortable, yet it was thought too much, and it was directed to be given at night only.

From this time he gradually deteriorated till his death. The dyspnoea was generally very oppressive, and he had frequent attacks of violent and continued retching. Generally either very restless, and even sometimes noisy and delirious, or in a soporose state. On the 6th of July the urine was entirely free from albumen, though still retaining the specific gravity of 1010; very abundant, pale, and watery in appearance. On the 8th the albumen again appeared. During the night he rose from bed, and attempted to throw himself out of the window. During the day he was in a soporose state, and passed the evacuations involuntarily; the respiration was stertorous, and completely arrested at intervals, for the space of half a minute. The tongue brown, and quite dry. On the following day he was more wakeful, being quite delirious, though not violent. At one time he complained of strange animals crawling over his bed; at another, he fancied that an evil spirit was placed at his feet. He disturbed the other patients very much by singing loudly during the night. On the 13th, no trace of albumen could be discovered in the urine by the usual tests; and this state continued till death, which took place on the 17th. The urine continued to the last to be passed in considerable quantity (about three pints per diem), though pale and watery, and of low specific gravity. Most of the symptoms described above continued till death. He seemed to die asphyxiated, respiration being very slow and irregular for some hours previously, and the pulse scarcely perceptible.

Inspectio cadaveris post mortem horas 40.

—Body much emaciated; feet and ankles alone oedematous.

The *thorax* contained much yellow serum; a few shreds of soft lymph on the pleura of both sides. In the upper part of the right lung, which was attached to the walls of the chest by old adhesions, was a dark-grey circumscribed induration, beneath which was a small empty cavity, having some largely dilated air vesicles around it. In the apex of the left lung, also, was some induration of a similar kind. The base of both lungs was dark-red, and much congested. The left ventricle of the heart was dilated, and much hypertrophied. The anterior lamina of the mitral valve, and some of the chordæ tendineæ, were thickened by a deposit of opaque lymph. The mitral valve was free from disease. The weight of the heart was $15\frac{1}{2}$ ounces.

The *abdomen* contained no serum. The liver was considerably displaced downwards, so as to reach as low as the umbilicus, but was smaller than usual. There was a concavity on the anterior surface of the right lobe, covered with a dense opaque false

membrane, of considerable thickness; a similar patch, of smaller size, was on the left lobe. The liver was of a dark colour; its substance was hard, but easily lacerable; weight 2 lb. 3 oz. The right kidney was much atrophied, being not quite two inches long. The capsule was strongly adherent. On removing this, the surface of the kidney was seen irregularly lobulated and granular, the granules being as large as cardamom seeds. Along the convex margin were numerous transparent vesicles. The cortical structure was quite gone, the bases of the pyramids being level with the surface. The substance of the kidney was firm, and of a dark red colour. The left kidney was little reduced from its natural size. The surface was irregular, with granulations of a smaller size than in the right kidney. The general colour was a dark red, but there were patches of a paler more albuminous appearance interspersed. The substance was firmer than that of the right kidney. A group of small vesicles was formed in the surface, near the upper end. The weight of the kidneys, without the capsules, was—of the right kidney, 1 oz.; of the left kidney, 4 oz.*

The whole inner surface of the stomach presented patches of striated and punctuated vascularity, and some ecchymoses of a dark colour. There was some puckering of the posterior part of the lesser curvature; and at this part was a small circular ulcer of the size of a pen. The ulceration seemed to pierce both mucous and muscular coats; it appeared of long standing, and was not surrounded by any increased vascularity; the margins were raised and indurated, and there was much thickening of the coats of the stomach for some distance around. The pylorus was healthy; there was no appearance of scirrhus of any part.

In the *head*, the arachnoid covering the hemispheres of the brain presented opacity following the course of the fissures between the convolutions. There was increased vascularity of the pia mater; in different parts were seen small spots of sub-arachnoid hæmorrhage. There were numerous opaque deposits on the arteries at the base of the brain, projecting like small granulations. In the choroid plexus was some opaque white granular matter, almost like tubercle.

The first object in the treatment was to improve the digestion and promote the action of the liver, for the dyspeptic symptoms were the most prominent at the time of his admission; the probability of success, however, was much diminished by the co-existence of organic disease of the kidneys, and, perhaps, of other organs. Afterwards, tonics combined with diuretics were administered

* A wax model of the kidneys is preserved in the museum of University College.

to promote the secretion of urea, which was very deficient in the urine. The kidneys, however, seemed too far diseased to admit of being stimulated to a more healthy action; the specific gravity of the urine was not raised, though the quantity of albumen was increased rather than diminished, as the cure advanced. The amount of urine secreted was rather above than below the natural standard, yet the œdema of the feet was permanent till his death.

Christison remarks that, except in cases of *diabetes mellitus*, a continued dropsical state, in connection with a large secretion of urine, may be regarded as a proof of the existence of granular disease of the kidneys. He explains the continuance of anasarca with an increased secretion of the watery parts of the urine in this disease, by considering that the tenacity of the blood, from the diminution of its albumen and hæmatin, increases its tendency to transude.

As the disease advanced, obstinate vomiting, with violent efforts at retching, became a frequent symptom, so much so that, in conjunction with the pain at the epigastrium, and occurring in a patient much emaciated and with very fallow complexion, it led to the suspicion of scirrhus of the stomach. Chronic vomiting is, however, a very frequent symptom in granular disease of the kidneys, and may be regarded as such in this case, though it is difficult to say how much this distressing symptom might have been dependent on, or aggravated by, the deep circular ulcer found in the smaller curvature of the stomach on the post-mortem examination. This kind of chronic ulcer frequently progresses, even to perforation, without previously producing any symptoms; at other times, pain, sickness, and many of the symptoms of cancer, are produced by it. The obstinate vomiting was generally best relieved by a full dose of calomel, which frequently will quiet an irritable stomach when all other means prove inefficacious. Some degree of shortness of breath existed from the time of the patient's admission, and this gradually increased till it became a most distressing symptom. The physical examination of the chest did not discover sufficient disease of the lungs to account for the severity of this symptom: it must be referred, in a great measure, to the diseased state of the blood, overloaded with carbon and nitrogen, in consequence of the imperfect action of the liver and kidneys, two of the great excreting organs, and thus throwing more work upon the third, viz. the lungs. It is not, however, easy to give an entirely satisfactory explanation of the dyspnoea which occurs frequently in cases of albuminuria; for, though a frequent, it is not a universal symptom in this disease, even up to its fatal termination, as is shown

by the former case of Wilson, where, with more serious disease of the respiratory organs, and in connection with an almost complete suppression of urine, there was very little complaint made of dyspnoea. Stramonium gave some relief to the paroxysms, but the narcotic effect of opium in deadening the sensation seemed of more avail.

As the disease advanced, many of the symptoms of derangement and oppression of the brain, which frequently present themselves in the latter stages of albuminuria, (probably from the circulation of blood poisoned with urea through the brain) began to appear. Great drowsiness at one time, at another time restlessness and various hallucinations were produced, adding greatly to the distress occasioned by other symptoms.

Till the end of June, the amount of albumen in the urine was slowly on the increase; it then much diminished, and at length no trace of it was discovered by the most careful examination. As the quantity of urine, *per diem*, continued much the same, the sp. gr. sunk in proportion to the removal of the albumen, showing that the disappearance of albumen was not to be considered a favourable symptom, as the healthy ingredients did not take its place.

The total cessation of the respiratory movements, sometimes for a full minute, occurring at intervals some days before death, was very remarkable: this did not depend on unconsciousness either in general, or to the sensation of dyspnoea in particular, but seemed the result of inanition; the anorexia and sleeplessness under which he had suffered for some time, having produced a state of emaciation and debility very extreme.

Symptoms of a low inflammatory state going on in the lungs presented themselves a few days before death, constituting (as in the case of Wilson), the *pneumonia agonizantium* of Laennec; the expectoration became rusty and rather viscid, and some crepitation was heard posteriorly at the base of the lungs.

The existence of fluid in the cavity of the chest, discovered on the examination after death, had not been detected previously, and had most probably been effused but shortly before the close of the disease. When the chest was last examined, crepitation was heard down to the base of the lungs, which could not have been the case had a fluid effusion intervened at that time. Probably this had been found out during the long protracted dying state which frequently produces such a result, and which was the more likely in a case like this, where the blood is in a diseased and unusually fluid condition.

The kidneys presented a well-marked example of the granular degeneration; in

one of them, arrived at an advanced stage. Any further remarks on the *post-mortem* appearances will be reserved for a subsequent occasion.

REPLY FROM THE SURGEONS OF THE LIVERPOOL NORTHERN HOSPITAL,

TO THE PAPER PUBLISHED BY J. P. HALTON,
IN OUR NUMBER FOR DEC. 29, 1843.*

To the Editor of the Medical Gazette.

SIR,

We, the undersigned, shall feel obliged by your inserting, in the next number of your *GAZETTE*, the accompanying reply to a paper published in a recent number of the *GAZETTE*, by J. P. Halton, Esq., entitled "The Results of the Great Operations of Surgery."

Your obedient servants,

WM. GILL,

JOHN M. BANNER,

HENRY STUBBS,

WM. HENRY BAINBRIDGE,

Fellows of the Royal College of Surgeons
of England, and Surgeons to the
Liverpool Northern Hospital.

Feb. 1, 1844.

In a paper recently published by Mr. Halton in the *LONDON MEDICAL GAZETTE*, an attempt has been made to prove, that the capital operations in surgery, performed in the Liverpool Infirmary, have been followed by a rate of mortality very much below what has occurred in other similar institutions.

The objects of Mr. Halton in this publication appear to be—

Firstly, To laud the superior salubrity of the situation of the Liverpool Infirmary, and its more perfect management.

Secondly, To attach to the situation of the Liverpool Northern Hospital a source of evil to the public, calling for its suppression.

Thirdly, To show, by the results of the operations of a good surgeon, in a well ventilated and well managed institution, that the general results, derived by Mr. Phillips from the records of a number of hospitals in Europe and America, are either incorrectly stated, or are attributable to the bad surgery of their medical officers, or to an unhealthy site and bad general management.

To effect these objects, he compares the results of his own operations during a period of twenty-two years, with a table published in the *MEDICAL GAZETTE* by Mr. Parker, our house-surgeon, of the results of

amputations during a period of seven years in the Liverpool Northern Hospital; and with the results of 640 amputations performed in hospitals in Europe and America, collected by Mr. Phillips, and published in the same journal. When Mr. Halton attacked the surgical practice of the Liverpool Northern Hospital, we think he ought to have consulted a pamphlet published by one of us, in the Edinburgh Medical and Surgical Journal, in which the results of our operations in the severest forms are tabulated, and sufficient details given of the cases, to explain what he calls our "high rate of mortality." It is at least a satisfaction to know, that our mortality after amputations is below the average result recorded by Mr. Phillips of his 640 cases, although we cannot boast of such apparent superiority as that claimed by Mr. Halton for his own practice.

Mr. Halton has been encouraged, by the advice of a medical friend, to sacrifice his unwillingness to appear in too prominent a position for the advantage of the profession, "as it would probably induce other hospital surgeons to follow the example; by which means we might ultimately obtain the important general record, the want of which is so much felt at this crisis, to correct the, what I believe to be, erroneous assertions put forth to the disparagement of operative surgery."

Had Mr. Halton been better acquainted with modern medical literature, he might have known that he is not the first who has applied the science of statistics to the correct appreciation of the risk of an operation in surgery; and he might have learned to have made use of numbers intelligently and fairly. When the science of statistics was first systematically recommended by Louis, as a proper means of settling many of the differences of opinion in medicine and surgery, as to the relative value of certain modes of treatment, objections were made to its adoption by several very eminent practitioners, as leading with an appearance of exactness into great error. It was urged, that if a calculation be made upon observations incomplete, inexact, or collected with a biassed spirit, into what errors will it not lead? This is, however, no objection to the method, but to the abuse which might accrue from ill intention or ignorance. Does not Mr. Halton lay himself open to one or both of these charges. His results are calculations from facts, the number and nature of which he has kept back from a feeling of modesty, which prevents him placing himself in too prominent a position, but at the same time permits him to claim for his own practice a superiority over that of other surgeons attached to the first hospitals in Europe and America. We can assure Mr. Halton that there are many of these hospi-

* The length of this paper has compelled us to omit several of the Tables by which it was accompanied. Two of the most important will be found in a subsequent page.—*Ed. Gaz.*

tals in as salubrious situations, under as careful management, kept as scrupulously clean, and as well ventilated, as the Liverpool Infirmary. He cannot, therefore, under the flimsy veil of a complimentary reference to the pre-eminence of the Infirmary, its excellent site, and the careful management of its committee, conceal, that he would have it inferred that this extraordinary success is only referable to his own extraordinary merit.

Mr. Halton gives us the proportion of deaths to recoveries, after capital operations, during a period of twenty-two years, and places the success shewn to the credit of the Infirmary. During four years of this period he had no connection with the Infirmary; and if we understand aright his rather obscure explanation, he introduces the results of his own private practice. These, and the operations performed in the Dispensary, have nothing to do with the site and management of the Infirmary. He in another part more distinctly attributes the success to his own merit. In page 9, he says, "the *risk* appears to me to lie in the manner in which it (the operation) is performed." In the following page, he suggests that the high rates of mortality in other hospitals arise from the registry of badly performed operations, of which he gives two specimens as occurring in his own knowledge. We question the propriety and use of such allusions, and we feel ourselves called upon to state, for the information of those who do not understand them, that these mistakes did not occur in the Liverpool Northern Hospital, nor in the practice of any of its surgeons.

We regret with Mr. Halton, that from the want of materials he has been unable to give a record of the results of all the amputations which have occurred in the Infirmary since he has been its surgeon. Such a table fairly drawn out would be to the point. Can it be true that the only record of the surgical practice of that institution is contained in a brief statement of operations during two years? and that there is no other record of the surgical practice of his colleagues? Where is the return made to a Committee of the House of Commons, of the operations and accidents during the four years immediately preceding the establishment of the Liverpool Northern Hospital, quoted by Mr. Halton in his pamphlet?

If this report exist, and there be attached to it the nature of the diseases and accidents for which the operations were performed, a comparison of the several classes in it with the similar classes in the full report published by one of us, in the *Edinburgh Medical and Surgical Journal*, might be fairly drawn, as the Infirmary at that time received all the accidents occurring in the town, the greater part of which were transferred to the Northern Hospital after its

establishment. Mr. Halton's pamphlet, though first published in the *MEDICAL GAZETTE*, and consequently apparently addressed to the profession, is yet in its new form, with its luminous dedication to the committee, and its terminating appeal to the truly benevolent, evidently intended for non-professional readers; and upon these its conclusions, apparently fair, will produce the greatest impression. We have therefore great reason to complain of his omitting to mention, that there are some amputations attended with comparatively little risk, and others in which the chances of survival are small: the greater danger being, in general, in operations the results of accident, the least in those consequent upon chronic disease.

To place in a table of results such cases as of equal value is a deception. We should like to have Mr. Halton's views of the relative risks of amputations in different subjects, under the different circumstances of disease, age, sex, habits, and temperament; but we find he is prevented by the limits he has prescribed to himself, from entering into the question at all. Every where, as a comment upon the proportion of his deaths to recovery, he apologises for some of his deaths taking place where recovery, from the severity of the accident, could not be expected; but nowhere does he mention the number or relative proportion of deaths to recoveries after amputation for chronic diseases and for accident. The present limited accommodation of the Northern Hospital prevents chronic cases of surgical disease from being admitted in anything like the proportion to accidents that the chronic diseases in the Infirmary bear to the small number of accidents which are now admitted into that institution. May we not infer that Mr. Halton's report, as he calls it, is of operations in cases where accidents form the exception, and chronic diseases the rule? In the Northern Hospital, chronic surgical disease is rather the exception, and accident the rule. We conceive we are justified in this supposition by the following considerations. In all cases of amputation the risk from the operation is proportioned to its proximity to the body. In Mr. Halton's table the deaths from amputations of the thigh are one in eleven, whereas in the less dangerous operation of the leg they are as high as one in six. This apparent anomaly is easily explained. The most common amputation for chronic disease is that of the thigh, for white swelling of the knee-joint. This operation is most frequently performed in young subjects, and is, or ought not to be performed when there is a complication of visceral disease. A great number of these operations in an hospital would explain the success to which Mr. Halton lays claim. In our table of amputations performed in

the Northern Hospital in the course of nine years and two months, we have twenty amputations for disease of the thigh, and only one death. We have had, during the last two years, fifteen amputations from both accident and disease, and one death. In the practice of one of us, there have been no deaths consequent upon the amputations performed by him. It would be, however, very dishonest to point to this partial success as an indication of the superior surgery practised at our hospital. We refer to our table in the appendix for the severe nature of the injuries which have raised the mortality in amputations of the thigh to 1 in $7\frac{1}{2}$ *.

Cured Died.			
Of these, for Accidents...	10.	7	3
„ for Disease....	20.	19	1
	30.	26	4
Four deaths in 30; or 1 in $7\frac{1}{2}$.			

In the very admirable paper published by Mr. Phillips, in the *MEDICAL GAZETTE*, he states, as the result of his researches, that he found “in certain hospitals the mortality after amputation has exceeded 53 per cent.; in several it has not exceeded 12 per cent., and in one of the number, out of twenty amputations there has been only one fatal result.” Mr. Halton objects to Mr. Phillips not specifying the hospitals in which such extremes occurred, in order, we presume, that each should receive its appropriate censure or praise; but we conceive that in acting thus Mr. Phillips has exercised a wise discretion. He does not think that the great mortality in the one case, and the great success in the other, are necessarily indications of better or worse management; but points out in another passage how extreme differences in the results may depend upon differences in the nature of the accident or disease, and on differences in the general age, habits, &c. of the individuals operated upon in the several institutions. We will take the liberty of quoting a passage from Mr. Phillips’s paper, to which, if Mr. Halton had paid attention, he might have found a solution of the extraordinary difference, if it exist, between the results of operations in the Liverpool Infirmary, and in the Liverpool Northern Hospital. “It may be thought that there are many sources of fallacy in investigations like the present—that certain hospitals are placed under peculiar circumstances, and that the results furnished by them would not be a fair representation of the whole. It is true that there are many hospitals so situated, either permanently, or in particular periods, as to render it probable that the results of amputations would be very unfavourable. In certain manufacturing towns a large number of accidents are produced by machinery. In such cases the injury may not be limited to the limb, which it may be

thought prudent to amputate, and the death of the patient may be a consequence of the accident, and not of the amputation. Other hospitals may be peculiarly the receptacles of chronic disease. An improved system of treating such diseases may be employed there, and the number of amputations may be small; but from that very circumstance, from the operation being performed as a really last resource, the result of such amputations might be unfavourable.” “I have therefore selected such hospitals as would produce something like an antagonism in this respect, and would render the results shewn a fair representation of what actually occurs.” (*vide Phillips, MEDICAL GAZETTE*, vol. xxii, p. 459.)

We hope to be able to shew, from a reference to the tables in the appendix, that the accidents for which, in general, amputations have been performed in the Liverpool Northern Hospital, place it in the first category; and without taking credit for any improved mode in the treatment of chronic disease, we may attribute our inferior success, if it exist, in the amputations of this nature, to circumstances in the cases which place them in the category of operations performed as a really last resource. We think we may fairly infer that the Infirmary is now one of those hospitals which Mr. Phillips would select as producing an antagonism to the Northern Hospital.

A difference of opinion as to the propriety of operating at once after an accident, or of waiting until the symptoms of collapse have subsided, may produce great difference in the proportions of deaths to recoveries after amputation, according as either one or other of these plans is adopted exclusively. This is a dispute in which many eminent surgeons have taken different sides, and “*adhuc sub judice lis est.*” It is a question, whether it be wiser to run the risk of leaving the patient to die without operation from the irritation arising from the extreme severity of the accident, or to run the risk of adding to the depression of the nervous system by inflicting in the operation an additional injury. This dispute is well illustrated by the difference of opinion expressed with regard to the treatment of Mr. Huskisson’s melancholy accident.

It is obvious that in an hospital where one system, that of waiting, is exclusively adopted, there would be fewer deaths after amputations in such cases, because there would be no amputations performed until after the collapse had gone off, but it is doubtful whether there would be less mortality. We insist upon this distinction being attended to, because we find in Mr. Halton’s report, fifty instances of compound fracture in which amputation was not performed, but in which incisions were made and pieces of bone

* Amputations of the thigh in ten years, 50.

removed, of which eight died. Now without pretending to say that Mr. Halton did not exercise a proper discretion in not amputating in the cases where death took place, it will be seen from our *precis* of amputations, operation was performed in cases of equally severe complication, often with a fatal result, but at the same time sufficiently often with a favourable one to justify the propriety of the proceeding. In table III. (appendix), we refer to cases 2, 4, 5, 6, 7, 9, 22, 27, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, and 39, in which, from the severity of the complications, and the presence of severe collapse, no attempt was made to amputate, and the patients were left to the chance that collapse would subside, and the operation might be performed under more favourable circumstances. In one of these cases erysipelas supervened upon an individual in whom there were four compound fractures. In two others, extensive emphysema, complicated compound fracture of the leg, and fracture of the ribs. All medical men understand the extreme danger of this complication, which indicates more or less injury to the lungs. In table IV. cases 2 and 12, and in table V. cases 2, 7, 9, 11, 12, and 35, are instances in which amputations were performed in the case of severe complications, profound collapse, and hæmorrhage, and were followed by death. In table IV. case 1, and in table V. cases 10, 18, 19, and 36, are instances of amputations performed under similar circumstances of severe complication, with successful results. We refer to these tables in general, as confirmatory of our statement, that the accidents for which amputations have been performed are of extreme severity; and in those cases in which death has been the result, the amputation has been performed in the face of circumstances, in which, had we not been anxious to afford the patient the smallest possible chance, we might have been justified in not operating at all, and thus have saved our credit, by diminishing the proportion of deaths in our amputations, without, however, in the least diminishing the mortality in the hospital. In none of these fatal cases can death be imputed to the bad situation, or defective management of the hospital, as a large proportion of the patients sunk shortly after the operation.

Since the establishment of the hospital, there have been forty amputations for disease, of which five died; but of these five, two died some months after the stumps had healed, from causes having no connection with the operation, (vide table VI. cases 4 and 26,) one being pulmonary apoplexy, the other a sudden death, not explained, from inability to procure a post-mortem examination. The exception of these two cases reduces the proportion of deaths in amputa-

tions for disease, to 1 in 13 $\frac{1}{2}$. Of these amputations, one successful case was at the shoulder-joint, and another was a case, in which, in an extremely debilitated subject, both legs were removed, one five days after the other. Two operations of excision of the elbow-joint were successfully performed. The operation is attended with more risk to the patient from the extent of the injury inflicted, than many amputations of limbs. Two cases of ununited fracture, one of femur, the other of tibia, were cut down upon, the ends of the bones sawed off, and union effected. One operation of extirpation of a great portion of the os calcis, for disease, was successfully performed.

Table I. contains an account of the results of the treatment of simple, simple comminuted, and compound fractures, from the opening of the hospital, to the 31st Dec. 1843. From this table it appears, that there have been 907 simple, simple comminuted, and compound fractures, of which 755 were simple and comminuted, 152 were compound.

Of the 755, three died, being cases of fracture of pelvis; of the 152, six died, being all compound fractures of the lower extremities. Tables II. and III. contain the results of compound complicated fractures of the upper and lower extremities, which were not operated upon; of these there are 59 cases, of which 25 died—17 in the upper extremity, of which 3 died; and 42 in the lower extremity, of which 22 died. In these tables are contained the worst of surgical accidents, which have entered the hospital, and we call attention to the severe nature of the complications in the fatal cases, as sufficiently explanatory of the results.

In Mr. Halton's attempt to account for the very questionable "*pre-eminence*" of the practice of the Liverpool Infirmary, over that of the Liverpool Northern Hospital, he thinks it probable that the healthy situation of the Infirmary, its cleanliness, and superior ventilation, may have contributed to that success. We find no fault with the glowing eulogium upon the situation, cleanliness, and ventilation of the Infirmary; but we maintain that Mr. Halton's description of the disadvantages of the present Northern Hospital, is exaggerated and unfair. Although situated in the least fashionable ward in the town, where disease and wretchedness prevail to the greatest extent, it is yet by its situation, internal management, and ventilation, however imperfect, freed from all the evil influences which make Vauxhall ward so very unhealthy, and which have been so well described by Dr. Duncan. There is no building within one hundred yards of two faces of the hospital, and the nearest warehouse is at least two hundred yards distant. Opposite to a greater part of the third side,

in Leeds-street, is a large flag-yard, from which no mephitic exhalation can arise; between the hospital and the canal, are coal-yards, and from the canal no danger need be apprehended, its waters being constantly renewed by fresh streams from the country. We claim for the Committee of the Northern Hospital as great attention to cleanliness, and to its general management, as Mr. Halton attributes to the Infirmary Committee: and although our ventilation be not so perfect as we could wish, from the circumstance that the building was not erected for its present purposes, but has been formed from two large and excellent dwelling-houses, yet very great improvements in the ventilation have been effected by the attention of its managers. Erysipelas, the scourge of many hospitals, is now comparatively rare, and there have been very few cases of idiopathic erysipelas for some years. The evil influences denounced by Mr. Halton ought to produce their effects upon all cases, medical and surgical indiscriminately, yet we are prepared to shew, from the comparative mortality of the two hospitals, that the results are, if anything, in our favour. From an average of four years, we find the mortality, in the general cases admitted into the Northern Hospital, to be as low as $6\frac{1}{2}$ per cent., whereas, in the Infirmary, it is 7 per cent. The average mortality of 63 European Hospitals (German, French, Swiss, Belgian, Dutch, Italian, and English,) is $8\frac{1}{2}$ per cent. The nature of the cases may be roughly estimated by the duration of the treatment. The longer average duration will indicate the prevalence of cases of chronic disease. The average duration of the treatment during the last four years in the Northern Hospital, is 17 days. The average duration in the Infirmary during the last two years is 31 days. Supposing the daily cost of each patient, in each institution, to be the same, our patients cost the hospital a little more than one-half of the cost of the infirmary cases. The average duration of the treatment in three German, and ten Parisian hospitals, is $28\frac{1}{2}$ days. From these remarks we may infer that, in the Northern Hospital, the average of the cases is of acute diseases, as the duration of the treatment is short; and that its situation and management are not very bad, as the comparative mortality is small. Although we think ourselves justified in making these inferences from the facts stated in favour of the situation and management of the Northern Hospital, it is far removed from our belief that the same mode of reasoning applied to other hospitals ought, with justice, to condemn either their situation or management. There are circumstances in the history of these hospitals with which we are not acquainted, such as the number of beds, the nature of the dis-

eases which are admitted or excluded, the average age and condition of the patients, &c. &c., which, if rightly appreciated, would probably place the hospital making the worst return upon the level of that making the most favourable. We will illustrate this by two cases. In the Catherine Hospital, at Stuttgart, we have an average duration of $21\frac{1}{2}$ days, being indicative of the presence of acute disease, and not much greater than in the Northern Hospital, with an exceedingly low rate of mortality, being only $2\frac{1}{2}$ per cent. In the Hospital Neckar, in Paris, the average duration of treatment is from 33 to 34 days, and the mortality is as high as 13 per cent. The high character of the French hospital management prevents us from assuming the superiority in which the mere consideration of numbers, apart from other circumstances, would place us; and justifies us in supposing that our inferiority to the Stuttgart Hospital may be equally explicable by the consideration of all the circumstances. We believe that, in the Hospital Neckar, consumption forms a large proportion of the diseases treated; its duration is long, and its termination necessarily fatal. From the limited accommodation of our hospital, such cases are as much as possible excluded; and when admitted, the first favourable opportunity is taken advantage of for their removal.

The claim of advantage, in the nearer vicinity of the residences of the honorary surgeons to the hospital, is absurd. Mr. Halton should remember, that the hospital is for the benefit of the patients, and not for the convenience of the surgeon. How is it possible that a man can be the better for being carried at least a mile farther from the place of accident, with a fractured limb, complicated with hæmorrhage? At both hospitals he would receive immediate assistance from well educated resident medical assistants, members of the Royal College of Surgeons, quite competent to meet any emergency, and we are not aware of any case, in either medicine or surgery, under such circumstances, in which the delay of half or three-quarters of an hour in the arrival of the honorary officer is likely to produce any difference in the result.

We have a right to presume that the object of the subscribers to the public charities, in Liverpool, is to afford the greatest possible amount of relief to the sick poor. It is the duty, as it is the province of the medical men attached to these charities, to supply the information which their experience affords, of the best methods by which this object may be attained; and it is our opinion that they will more advance the cause of charity, by pointing out the defects in the management of their own institution, than by dwelling on their merits. A flaming self-

laudatory report satisfies the public with the good that is done, but is apt to turn away their attention from the greater good, which with the same means might be done. We are far from satisfied that the Northern Hospital is as efficient as it might be. We wish a better ventilation, and that the wards were less crowded; and we wish more especially, in the medical department, that we had fewer cases of chronic diseases, and more of the acute affections, for which such establishments are properly intended, and which we well know exist among the poor, and are treated at their dwellings, under the most unfavourable circumstances. It has long been the wish of the committee and medical board of our hospital, to remedy the two first defects, and we have now an early prospect of being able to do so, by the erection of a building adequate to the importance of the institution to the public. The medical men of the infirmary are equally well aware with ourselves that their wards are filled with cases of chronic disease to the exclusion of the more acute forms. The substitution of the latter for the former would swell the rate of mortality in both hospitals, but would nevertheless increase the utility of the hospitals to the public. It would be a means of offering, without disguise, to the contemplation of the more wealthy inhabitants, the full extent of the misery which prevails among their poorer fellow citizens, and which calls for relief,—a call which when heard has always been warmly responded to by the inhabitants of Liverpool. The machinery for effecting this purpose is at hand. The medical officers of the dispensaries, and the visitors of that most excellent charity the District Provident Society, come, in the

performance of their duties, into immediate contact with the objects of disease; and, if the former were to cooperate with the latter, in selecting the most fit objects for the public hospitals, and would the managers of the hospitals place at the disposal of these visitors the power of filling up their vacant beds, the objects of charity would be more effectually served, and the necessity of even more extended hospital accommodation clearly demonstrated.

We have laid before the profession a statement of the surgical practice of the Liverpool Northern Hospital, and have compared the results with those of the Liverpool Infirmary, and other institutions, as far as we have access to them, with the object of defending ourselves and the hospital from a most unjustifiable attack. We have no wish, from anything we have brought forward in our own defence, that conclusions prejudicial to the Infirmary, or any other medical charity, should be drawn; and it must be clear, from the grounds of our defence, that we do not think any such conclusions would be warranted. We should be sorry to think there is no room for improvement in any of our public institutions; the best way to arrive at the cause of any defects requiring remedy, is, by comparing the results of different managements and modes of treatment; and we are very anxious to cooperate with Mr. Halton, his colleagues, and the other medical functionaries, in exposing the defects in the management of our own, and other institutions; and we believe our success will be the greater, the more we carry on our investigation in the spirit of that charity which it ought to be our common object to promote.

Simple and Compound Fractures which have been treated in the NORTHERN HOSPITAL, from March 10th, 1831, to the 31st December, 1843, with the results.

UPPER EXTREMITY.

LOWER EXTREMITY.

78 Total.

Giving a total of 78 deaths in 1236 patients, admitted into the Northern Hospital, from January 1st, 1843, to January 1st, 1844, being one death in 15 6-7ths. Of these—

41 occurred in 507 medical cases, or 1 in 12 $\frac{1}{2}$
 37 „ 731 surgical „ 1 in 16 $\frac{1}{3}$

The average mortality of 63 European hospitals is 1 in 11. The greatest mortality being in the Maria Hospital, at St. Petersburg, being nearly 1 in 4; the least in the Catherine Hospital, at Stuttgart, being 1 in 40. In the Liverpool Infirmary 1 in 13 $\frac{1}{3}$. If we add to the patients in the Northern Hospital 352 out-patients, the mortality is 1 in 22 $\frac{1}{3}$. The average duration of treatment for each patient in 3 Germa and 10 Parisian hospitals, was 28 days. The maximum being 66 days in the Venereal Hospital at Paris, the minimum 20 days, in the Catherine Hospital at Stuttgart. The average duration of the treatment for each patient in the Northern Hospital is for 1843, 23 $\frac{1}{3}$ days, that of the medical patients being 19 3-5th days, that of the surgical patients 24 4-7th. The average duration of the treatment of each patient in the Liverpool Infirmary was 35 days, in the year 1841.

It will be seen by the above table, that 27 patients, out of 78, died on the day of admission, being such cases of disease or accident as are beyond the reach of either medicine or surgery, and 15 died within six days, the average duration being 3 $\frac{1}{3}$ days; consequently, 42 out of 78 of the deaths necessarily took place under circumstances of extreme gravity of disease.

99 medical patients were discharged from the hospital within six days after admission, being either slight cases, incurable, or irregular.

The out-patients being excluded from the general return in these calculations, they differ from some in the 18th page of the pamphlet.

CONTRIBUTIONS
TO THE
PHYSIOLOGY OF THE HUMAN
OVARY.

By CHARLES RITCHIE, M.D. Glasgow.

(For the Medical Gazette.)

[Continued from p. 365.]

PART I.

SECTION II.—*Cases in which menstruation had existed regularly, the parties never having been pregnant.*

1. ISABELLA K—, aged about 17, sober, industrious, and unmarried. Catamenia regularly present for eight periods before death, and the last time ten days before her decease. Cavity of uterus of a sooty colour. Ovaries very large and turgid, each measuring nearly two inches in length, and proportionably thick. No cicatrice was perceptible on their surface, but this was studded in both with small prominent vesicles, of a red colour, like those which we see before puberty, and there were, also, one or two capillary-sized points, in which the peritoneal coat was abraded, and slightly punctulated, as if from the rupture of similar vesicles. Internally both ovaries were filled with vesicles, one of which was very large, and its coats extremely vascular. There were two small and faint-coloured melanotic spots, corresponding to vesicles, the coats of which were, however, unaltered in their structure, and unconnected with any external lesion. No trace of a vesicle which had been affected by menstruation was perceptible.

2. Jean S—, aged 18. Menstruating thirteen days before death. Uterus small; the vessels of its entire inner surface greatly congested with black blood. Ovaries of normal length, but not plump, and very pale. No cicatrice on either, but peritoneal covering studded with numerous small bluish spots from adjacency of Graafian vesicles to its inner surface. In the right ovary were numerous vesicles, one as large as a dried garden-pea, and vascular, others of the size of mustard-seed, and some with their coats congested. In the left there were also many vesicles, although smaller and paler than those in the other, and on its superficies there was one minute red puncture, such as is

sometimes seen in infancy, or before menstruation or puberty. No fatty tissue, yellow cysts, melanotic spots, or other indication of a Graafian vesicle having been acted upon by menstruation. Character of woman respectable, and os uteri that of virgin.

3. Catherine B—, aged 19. No children. Respectable character. Menses regular, and present nine days before death. Inner surface of uterus red, and fluid in tubes of a reddish colour. Both ovaries large, and mottled by livid maculae from small vesicles approaching the inner surface of the peritoneal coat. One ovary also exhibited some reddish point, which were small Graafian vesicles already imbedded in its peritoneum and partly projecting from its external surface, and, also, three small cicatrices scarcely perceptible—one corresponding to a cavity of size of a garden-pea, lined with matter having a lively resemblance to convoluted brain garnished with its veins. This was of the thickness only of post-paper, and seemed to be made up of an inner membrane, and of another, more external, which was vascular, while external to this was a third, by which it was connected with the stroma of the ovary. The other ovary was marked by one or two irregularly-shaped cicatrices, and under the principal was a brainy cyst, of size of a large hemp-seed, and throughout the gland, an immense number of small-sized Graafian vesicles in their natural state.

4. Agnes M—, aged 36 years. Unmarried. Had not had a child. General health good. Died of typhus. Catamenia regular, and present ten days before death.

One ovary. Its free edge drawn into a point by a mammillated tumor, almost as large as a small raisin, which gave the ovary a conical form, the tumor representing the apex. This tumor was covered by a thin transparent coating of the outer tunic of the ovary, through which ecchymosed spots and vessels containing dark blood were seen to rest on a ground of a light red colour, and on the point of the tumor was an opening smaller than a pin-head, in which was a minute piece of coagulum. At some distance from this was another similar tumor, but flaccid and smaller, and on the other parts of the ovary were numerous

strongly-marked fissures. On dividing the gland, the first tumor was found to consist of an elliptical cyst of nearly half an inch in length, filled with a recent coagulum of blood, its inner surface, formed by the coats of a Graafian vesicle, thickly injected with turgid vessels, but still diaphanous, and not admitting of being separated into laminae. The smaller tumor was constituted by what had been a large-sized Graafian vesicle, the coats of which remained turgid, but empty and without other changes. An elliptical yellow body, of small size, corresponding with the situation of one of the fissures, was also observed. Nothing remarkable in other ovary.

5. — — —, aged 22 years. Hymen perfect. Previous period of menstruation unknown, but the inner surface of the uterus had the dark, congested, and vascular look, which it has at, and for a short time after, the menstrual period — the minute vessels constituting this appearance being also covered with a white mucus, resembling that found uniformly in the fallopian tubes, and which is secreted also by the lining of the vagina. Ovaries large, and their surface indented and furrowed by numerous cicatrices. Internally were observed two sacs with yellow envelopes filled with blood of an extremely black colour, and in process of absorption; and also, in situation of what was, externally, a recent-looking tumor, of the size of a marrowfat-pea, having the peritoneal coat removed at its most projecting part for about the size of a barley-corn, but without any apparent opening, was a sac consisting of an inner delicate pellicle, and an outer, yellow-coloured, and thick coat, and containing a comparatively recent, but very solid coagulum, the periphery of which was indented with a number of fissures, corresponding to certain irregularities or duplicatures of the inner surface of the cyst, dependent on its begun corrugation.

6. Agnes N — —, aged 19: unmarried. No children, and the appearance of the uterus precluded the possibility of a recent abortion. Menses present nineteen days before death. Both ovaries presented cicatrices and ecchymosed spots, the latter apparently more recent than the former, and having their centres perforated by foramina; and one of the cicatrices, around which the ecchy-

mosis had disappeared, had also an opening leading into a cyst, of about the size of a small pea, lined with a very delicate transparent membrane, through which the yellow, or, in this instance, dirty cream-coloured matter on the external membrane was perceived. Adjoining to this was another body, corresponding with the most recent external ecchymosis, with which it was connected also by a foramen. It was of the size of a garden-pea, seemed covered internally by an extremely delicate diaphanous membrane, which was stained with red blood, and veiled a deposit of dirty cream-coloured matter, of the consistence of thin paste, which lay on the inner surface of the yellow opaque external covering of the cyst.

7. — — — M.R — —, æt. 45. Menses present. Various dark inky points in ovaries, which are of a fleshy consistence, and in the one ovary there is one, and in the other two vesicles, apparently Graafian vesicles, one of them as large as a nut, on which the peritoneum is absorbed to a few fibres, and the vesicles protrude from the ovary, covered only by their proper coats, and filled with an amber-coloured fluid, which coagulates with heat.

8. — — —, æt. 40. Menstruated two months before death. Uterus large, but healthy. Both tubes shut, and adherent to ovaries. Ovaries large, and marked with indentations, and one of them with two minute vesicles slightly elevated above the surface. Substance of glands gave out fluid from innumerable points when cut, but few vesicles of any size were observable; and in situation of three of the cicatrices were corresponding yellow bodies without any blood in their centre, but having an accurate miniature resemblance, when cut vertically, to the hemispheres of the brain, both in the whitish, opaque, yellowness of their colouring, and the convoluted indented arrangement of their substance. In the centre of each was a line running in the direction of the length of the body, and filled with what might either be an extremely delicate inner membrane, or transparent lymph. Externally the yellow substance was covered by a delicate diaphanous membrane, through which it shone like a cartilage, and with which it could be dissected from the ovary.

9. ———, æt. 25. Menstruated six days before death, which was from fever. Apex of one ovary occupied by a mammillated tumor, perforated near its point by a small circular hole, which, when cut vertically, was seen to consist of a cyst containing a solid coagulum nearly deficient of its red globules, and so consistent as to admit of being cut through its centre, one segment continuing to cover one hemisphere of the cyst, and the other the other. These latter consisted of a gamboge yellow matter arranged in slender convolutions, on the interior of a thin indivisible membrane, but no internal lining covering: this matter could not be detected either by the late Mr. Allan Burns, who gave me his valuable assistance in this dissection, or by my own efforts, after maceration in a solution of alum, and in warm water. No additional layer of membrane could be raised from the ovary in the bed of the cyst, and neither the sac nor the yellow deposit contained any visible vessels.

10. Marion B——, æt. 17. Menstruation of eighteen months standing, and regular, but last appearance not noted. No child. Habits good. Uterus and its orifice small; its inner surface pale. Ovaries of good size.

Right.—Free edge much denticulated at one point by an old cicatrix, the new matter forming the base of which is equal in size to that of a large split pea, and through this, a very vascular Graafian vesicle, of about the size of a hemp-seed, is seen rising: on opposite side of ovary from this is a second cicatrice, nearly as large as the first, and one or two of smaller size. Corresponding internally in the ovary to the last of the large cicatrices was a yellow, elliptical body, having something of a triangular form, from the conical elevation towards the surface of its upper or external edge, which was also serrated. The internal cicatrix, as it has been named, or line denoting the remains of the former cavity, was very well marked, and contained, at one part, a minute pale red coagulum. At one extremity of this body, owing to the absence at that point of an interposing internal cavity, the yellow walls of the cyst were about an eighth of an inch in thickness, and consisted of two parallel horizontal folds in close apposition, but quite distinct from each other; while

in the other parts, which were traversed by the slender internal cavity, they were, of course, only half the thickness, but their substance in different places was observed to be beautifully injected with red vessels passing from the ovary. Corresponding with the first mentioned large cicatrix, but deeper in the ovary than the vascular unbroken Graafian vesicle which occupied its immediate surface, and also in the situation of two of the smaller cicatrices, were hollow, corrugated bodies of a white colour, and porons or granular-looking tissue small, and comparatively indistinct in the latter, but well defined in the former, and when cut into exhibiting a texture not unlike delicate cartilage.

Left.—Externally, four cicatrices of moderate size, and apparently old, corresponding to one of which, internally, were the remains of a well-marked white body, similar to those in opposite ovary, except that it had not a spherical form, but consisted of rather horizontal laminae, its layers not gathered up into a little ball, but lying flat. Under another sac was a fawn or light stone-coloured cyst of the size of a split-pea, the walls of which were not thicker than writing-paper, and not at all corrugated; the central cavity remaining apparently of its original size, and occupied by a delicate fibrinous clot.

CASE OF EXTRA-UTERINE FŒTATION.

To the Editor of the Medical Gazette.

SIR,

WE beg to transmit to you for publication in the MEDICAL GAZETTE, the inclosed history of a case of extra-uterine fœtation, which was attended by us.

We have the honour to be, sir,

Very obediently yours,

G. W. CHARLETON,	} Surgeons.
Gloucester.	
J. W. WILLIAMS,	
Stamton.	

Gloucester, Feb. 9, 1844.

Mrs. Lake, æt. 46, of Ashleworth, who had previously three times been delivered with difficulty, and the loss of the children, again became pregnant, and was the subject of the following case.

In the end of September 1843, being, as she believed, five months gone with

child, pain commenced in her left side, since which period she has never been quite well.

January 11th, 1844.—The waters broke, and her urine became bloody.

24th.—Pain in the abdomen commenced.

25th, two o'clock A.M.—The pain which began yesterday morning increased to the present time, and now is constant, and extends over the whole abdomen; it is accompanied by great tenderness when pressure is applied.

The patient is within ten days of the period when she expected to be confined.

Some fluid which escaped from her when being assisted to her bed was of a purple colour, and had a very disagreeable smell.

By examination per vaginam I could neither discover the os uteri or fetus.

Capt. statim Tra. Opii. ʒss.

9 o'clock A.M.—The opium produced ease, and the discharge has gradually abated.

The pain within the last hour has returned, but not in a violent form. She has not made water for twelve hours. On the introduction of the catheter only about a tea-spoonful of urine flowed, and that was followed by a small quantity of pus.

Rept. Tinct. Opii.

My friend, Mr. Hooper, who for twenty-five years has most successfully practised midwifery, &c. at Staunton, favoured me with his counsel. He examined the patient, and also passed the catheter: the result was such as I had arrived at; he prognosticated a fatal issue, and observed, that "he had never met with such a case before," and recommended me to watch the patient.

12 o'clock P.M.—She is free from pain, and feels disposed to rest; the discharge continues in a slight degree.

26th.—She slept moderately well; her breathing is a little difficult; bowels have not acted since 24th.

Capt. Haust. Aperients, 3tis horis

7 o'clock P.M.—Bowels have not been evacuated. Pulse, which hitherto had been good, is 100; breathing is more difficult. She appears somewhat exhausted, and has great pain in her abdomen.

Capt. Statim. Vini. Ipecac. Tinct. Opii. aa. ℥xx.; Mist. Camph. ʒj.; and administer a little gravy soup at intervals.

12 o'clock P.M.—She has been relieved somewhat.

Rep. Haust.

27th, 3 o'clock A.M.—A sudden change has taken place for the worse: she has been sick; pain of abdomen returned with great violence. Pulse 120, and feeble; difficulty of breathing is more distressing; and she requires to be bolstered up in bed.

Capt. statim. Tinct. Opii. ʒss.; Aque ʒj.

She soon afterwards vomited, and appeared to be sinking. A little brandy and water revived her.

8½ o'clock A.M.—Mr. G. W. Charleton arrived from Gloucester, whose opinion and assistance I was most anxious to attain. He examined the patient, found the os uteri was dilated and soft; discovered the head to be the presenting part, recommended turning, and the administration of secale cornutum.

Capt. statim. et rept. post horæ quartam partem Secali Cornuti, ʒj.

9 o'clock.—I introduced my hand without finding any obstruction; the head presented, and felt as if surrounded by the amnion containing fluid. In bringing down a leg the cuticle peeled off it.

Pain in back, with periodical uterine pains, were experienced. Though slight extension of the leg was made, no descent was observable.

To take brandy and water every quarter of an hour, and gruel occasionally.

12 o'clock.—Her extremities became cold, and her pulse more frequent and weak. She vomited, and her speech altered.

Capt. Statim. Tinct. Opii. ℥x.

She rejected it.

Take ammoniac and brandy and water, which was also vomited.

I again made extension of the leg, and found it perfectly unyielding.

7½ o'clock.—Pulse became imperceptible; eyes fixed; she vomited, was convulsed, and died.

Mr. Charleton begs to confirm the foregoing statement, and to append the following notes:—

When he visited Mrs. Lake, January 27th, 8½ o'clock A.M. (about five hours before she died), her features were contracted and anxious; pulse was 120, small and feeble; tongue

clean; breathing very hurried, and short; pain in left side was severe, particularly when she lay upon it or was moved. Chest when percussed was sonorous. A slightly reddened discharge existed; it had moistened a napkin which had been applied two or three hours.

The os uteri was dilated to more than the size of a crown-piece; its posterior half was defined, while its anterior was very obscure. Two bodies appeared to proceed from, and to be connected with, the interior of the os uteri: the one was about a third of an inch in thickness, and two inches in breadth, and felt somewhat like the edge of a placenta; and the other was thin, and resembled a part of a ruptured amnion.

By changing hands, and using my left fingers, I detected the fœtal head. It was situated anterior to the bodies just described, and was separated from my fingers by a thin texture. It very readily receded from the pressure I applied to it.

As the patient had endured more or less pain; had experienced some discharge, and had been losing strength for three days; as the os uteri did not by its size present obstruction, and as it was possible that the discharge might be owing to a partial detachment of the placenta from the os uteri (although the pulse was 120, and so feeble as hardly to leave a hope of success), I suggested that *secale cornuti* (3j.) be given immediately, and that a few minutes afterwards, when uterine action as its effect might be anticipated, that the operation of turning be performed.

As a quarter of an hour elapsed without pain, a second dose of ergot was administered.

Turning was accomplished with ease both to the patient and operator, and during its performance much flatus escaped from the anus, but not any hæmorrhage from the vagina.

When I subsequently applied extension to the child's leg I experienced a resistance as firm as if the fœtus had been adherent to the woman's pelvis.

The pain which followed the administration of the *secale cornutum* the patient described as affecting her back, being of a forcing down kind, and periodical, such as she had suffered in previous confinements.

Half-past 10.—As expulsive action

had not assisted in the birth of the fœtus, and the patient was exhausted, it was agreed that brandy, arrow-root, and rest, should be trusted to for a while, and that manual assistance should be repeated if symptoms should render it eligible.

Post-mortem examination, Jan. 29th.

The abdomen is large, livid, and tympanitic.

Immediately on cutting through the lower part of the abdominal muscles and peritoneum, flatus escaped; and on elevating the parietes a full-sized fœtus presented itself to view. Its back was upon the os pubis, its head in the left iliac region, and one leg was in the vagina, while the other was near the left hypochondriac region.

The cuticle of its back and scalp was considerably detached, and the subcutaneous tissue of its back, head, and scrotum, was greatly distended with air.

The cavity in which the fœtus was placed was bound anteriorly, above, by the peritoneum which lined the abdominal muscles, and below, by the pubis and upper part of the bladder. Posteriorly, by the anterior surface of the uterus, and by the intestines, and inferiorly, by the upper portion of the vagina, with which it directly communicates by means of a large opening.

The above-named boundaries were lined and united by the membranes of the ovum, and by a little lymph, which, together, formed a layer hardly as thick as brown paper, which layer readily peeled off the parts it was united to.

The only recent lymph discoverable was attached to the anterior wall of the cavity in which the fœtus was found, viz. that formed by the abdominal muscles, &c. It somewhat assumed a purulent character.

The placenta was situated in the left side. It was united to the fore part (the outer surface) of the uterus, to the left side of the inner surface of the ovum, in the iliac fossæ, and, through the medium of the membranes, to a small intestine. To the latter it was most firmly, but least extensively, adherent. The portion of intestine to which it was fixed was connected with another fold of the same intestine by a small band of organised lymph.

The placenta was as large as usual, but rather thinner, of a lighter red colour, and was fibrous, as if composed

of smaller and less tortuous vessels than commonly is the case.

The uterus was entire. Its length was six and a half inches, its breadth five inches, and its thickness three inches. Each side of it was an inch thick. Where cut, it was white, and the largest vessels which were divided were the size of crow-quills.

Where the ovum was peeled from its surface it was smooth. Its cavity was rough, and reddened as if by the formation and attachment of imperfectly formed membranes.

The os uteri readily admitted fingers from the vagina. Its anterior lip was lost in the wall of the new cavity, and the soft bodies felt in the os uteri before turning was performed, could not again be recognised.

The right round and broad ligaments were distinct, but those of the left side were lost in the tissues of the abnormal cavity; hence the ovum was extra-uterine and tubular.

The bladder was contracted, and on being cut into it displayed at its back and lower part an ulcerated opening the size of a shilling. A finger from the vagina readily entered that opening.

The general cavity of the peritoneum was free from inflammation, and did not contain any effused fluid.

QUERIES.—May not the great decomposition of the fetus be attributed to the admission of air into the ovum by an opening formed when the waters broke, a fortnight before the patient died?

May not the dead halt which was experienced when extension was applied to the fetus, have been produced, 1st, by the weight of the child's body having been opposed to the force applied (as the patient lay rather on her belly); 2dly, by the pubis and uterus having presented mechanical obstructions to its direct progress; 3dly, by the leg of the child, which was above the uterus, having, when extension was made, pulled down the uterus, and so wedged the brim of the pelvis; and 4thly, chiefly and lastly, by the absence of that most powerful aid, uterine propulsion?

As the bladder was ulcerated (probably from the pressure of the head after the breaking of the waters), is it not likely that a similar absorbing pro-

cess facilitated the communication between the ovum and the vagina, and that nature so promoted delivery?

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

Principles of Medicine; comprising General Pathology and Therapeutics, and a brief general View of Etiology, Nosology, Semeiology, Diagnosis, and Prognosis. By C. J. B. WILLIAMS, M.D. F.R.S. London, John Churchill. Pp. 400.

THE great advancement made in those sciences which are justly considered as indispensable elements of a sound medical education, has not been attended by any thing like a proportionate improvement in our knowledge of the principles of diseased action. The necessity of being thoroughly conversant with those laws which regulate the animal machine, in order to attain to a right comprehension of the living human fabric in a state of health, is acknowledged on all sides: the same materials, of the self-same structure, are those which are implicated in disease; yet the body is then regarded as having assumed new relations—to have become amenable to new laws; and the treatment of disease, as a matter of course, is conducted on principles *sui generis* (whenever principles are consulted in the treatment), as if the phenomena of diseased function or structure could have no possible connection with those phenomena by which they are characterised when in a healthy state. In fact, there still exists, between practical medicine and its accessory sciences, a vast chasm, which the medical practitioner considers foreign to his vocation—may even hostile to his interests to approach. It usually happens that, in first addressing himself to the great business of his profession, the care of the sick, the young practitioner altogether loses sight of, or lays aside as useless or inimical to his future success, all those principles which, in the early part of his medical career, he had been taught to contemplate as pertaining only to the body in its normal condition. Physiology is not the pro-

vince of the medical professor, who erroneously presupposing, on the part of his pupils, a capability of applying its laws (should he know them) to the elucidation of disease, rigorously restricts his lectures to special details. Nosological arrangements are notoriously worse than useless in practice, owing to the multitude of phases under which disease presents itself: and the practitioner is therefore left pretty much to his own ingenuity for whatever general principles his own personal experience may lead him to adopt. As these principles must correspond with the tone of mind and habits of reasoning of the individual, we need be at no loss to understand why there exists that conflict of opinion amongst medical men, at once the characteristic and opprobrium of the profession.

The work before us is well calculated to supply a most important link (above hinted at) in the chain of medical education. Disease is justly designated by the author as *merely a changed condition or proportion of function or structure*. "Disease can be known only by comparing the altered functions with a healthy standard, which it is the grand object of the accessory sciences, especially physiology, to define. Throughout our examination of diseases, the principles of pathology derived from a comparison with the principles of physiology are being continually exemplified; and those who commence the study of medicine by attempting to learn the details of diseases, are like those who would master all the facts of chemistry without the knowledge of chemical affinity and definite proportion."

The term "principles of medicine" is used by Dr. Williams as synonymous with the terms "elements or institutes of medicine," deduced "partly from anatomy and physiology," but "chiefly from a generalization of facts observed in an extensive study of disease itself, and its effects on the living and dead body." The large number of facts he has succeeded in bringing together in support of this position are arranged after the following method:—

1st. Etiology, or causes of disease, divided into predisposing, exciting, and non-cognizable, or such as are referred to epidemic, endemic, and infectious influences. Food and medicine are

reckoned among the exciting causes; and certain doctrines on the animalcule and parasitic origin of certain epidemic and infectious diseases are considered under the third class. The author's views are better collected from the section "pathology proper," or "pathogeny," which comprises four-sixths of the bulk of the work. This section is divided into functional diseases, and diseases from perverted nutrition. Lastly, we have a concise disquisition on the classification of diseases, on prognosis and modes of death, and on prophylaxis and hygienics.

The terms, primary element and secondary element, heretofore restricted to the physical sciences, more especially to chemistry, are now, we believe, for the first time, rendered significant of corresponding simple and complete conditions of the body under disease. The primary elements of the functional or dynamic diseases are exemplified, 1st, in the excess, deficiency, or perversion, of certain well-known elementary properties of tissue, *e. g.* irritability, tonicity, sensibility, and the elementary function, nervous sympathy and reflexion; 2d, in certain changes of the elementary constituents of the blood. As examples of one or more of these three conditions of the elementary functions, we find (irritability) convulsions, spasm, cramp, and the susceptibilities of nervous persons, the effects of such poisons as tobacco, which produce death by destroying the irritability of the heart; (tonicity) the effect of cold and heat on contracted tissues, but "more distinctly characterised by increase of interval between the heart's beat and distant pulses; (sensibility) neuralgia, spinal tenderness, coma in certain apoplexies and narcotic poisoning, various nervous sensations occurring in hysterical females; (reflex function and sympathy) movements of the limbs, such as can frequently be produced in coma and paralysis by mechanical irritation applied externally, cardiac palpitation from intestinal irritation, spasm of the bronchi in asthma, traumatic tetanus; (constituents of the blood) discoloration of the red particles in malignant fevers. The black matter of melanosis seems to be the colouring matter of the blood in an altered state. The author asserts this to be true in spurious melanosis of the intestines

(*fibrin and colourless globules*). This paragraph contains a highly interesting exposition of the changes the blood undergoes during coagulation, the forces determining and modifying the separation of the fibrine from the red particles, the peculiarity in the aggregation of the latter, and the nature of the buffy coat, with their value as diagnostic signs.

The proximate elements of func-

Hyperæmia, or excess of blood			RESULTS.
	General—Plethora	{ with motion increased—Sthenic diminished—Asthenic }	Hæmorrhage, Flux, Dropsy.
	Local	{ with motion diminished—Congestion increased—Determination of blood partly increased } and partly diminished } —Inflammation	

Dr. Williams is of opinion that the known physical properties of the living body will account for the chief phenomena which mark the inflammatory process, and appears extremely unwilling to admit certain arguments in favour of the existence of vital attractions and repulsions, adopted by Haller and others, and recently advocated with much ability by Dr. Alison. We agree with him, that if the nature and effects of inflammation can be explained by reference to ascertained properties, it would be needless and unphilosophical to assume the existence of others which are mysterious and unknown. Without entering more at length on his line of reasoning, the following may be taken as a tolerably correct summary of the author's opinions on these points. 1st, obstruction to the passage of the blood in the vessels actually inflamed, an assertion which coincides with the microscopic observations of Thomson, Hastings, Kaltenbrunner, Marshall Hall, and of the author himself; 2d, increased flow through the vessels in the immediate vicinity of the inflamed vessels. These two conditions will account for the apparent inconsistency of the author's definition of inflammation, *e.g. local hyperæmia with motion partly increased and partly diminished*. The nature of this obstruction, the grand problem, to solve which so many theories have been devised, is said to be the result of the following changes. 1st, the rapid production of numerous white (fibrinous) globules, which adhere to the sides of the inflamed vessels; and, owing to this circumstance, 2d, retardation, and ultimately obstruction,

tional diseases is a legitimate distinction arising out of a combination of one or more of the foregoing primary elements: under this head we find anæmia and hyperæmia. We subjoin a tabular arrangement of hyperæmia; and, with an extract on the phenomena attending the process of inflammation, we must conclude our notice of the work.

to the passage of the red globules. "The production of these globules, in local hyperæmia, must probably be considered as an ultimate fact in the history of inflammation and nutrition." Spasm of extreme vessels (Cullen), active dilatation, vital turgescence, turgor vitalis, inflammatory erection, can no longer have even a fancied existence. The degree of proclivity to inflammation is determined by the facility with which these *obstruction globules* are produced. The chief elementary components of inflammatory effusion are compiled by the author from the recent microscopic discoveries of many observers.

1. *Molecules*, immeasurable from minuteness, each appearing as merely a dark speck (*smaller primitive molecules*, Gruby).

2. *Granules* (Gerber, Addison), measuring from $\frac{1}{125000}$ to $\frac{1}{80000}$ of an inch, appearing as a light spot surrounded by a dark circle (*larger primitive molecules*, Gruby; *disks*, Barry).

3. *Fibrils*, extremely fine, forming the chief solid of fibrine and the buffy coat of the blood.

4. *Lymph or exudation corpuscles*, measuring from $\frac{1}{80000}$ to $\frac{1}{7000}$ of an inch (Gulliver), composed of granules and molecules (nuclei and nucleoli), and sometimes enveloped in a cell.

Pus globules appear to be enlarged modifications of the last; and so are globules of mucus, and which, with nucleated epithelium particles, are commonly formed in the effusions from mucous membranes. *Yellow tuberculous* matter has been distinctly proved, by the researches of Gerber, Gulliver, and Addison, to consist of disintegrated or

degenerated exudation corpuscles or granules.

The mode in which the exudation corpuscles make their way through the coats of the vessels, so as to appear at their exterior, is not known. Pus globules, besides being larger than their progenitors, the exudation corpuscles, differ from them in being more distinctly vesicular, and containing a fluid as well as granules. But their great distinguishing characteristic is their want of cohesion; and in proportion as they predominate, they impair the consistence of fibrin or mucus with which they may combine. Pus effused into cellular and complex tissues also impairs their cohesion, and leads to the destruction of their substance; hence suppuration consists in not only a formation of pus, but also its substitution, more or less, of the inflamed texture. For this reason, suppuration, more than effusion, may be called a termination of inflammation; for the inflamed vessels are in a great part destroyed. It is assumed that absorption is still active in an inflamed part, and the assumption is warranted by the fact that the absorbent vessels, lacteals, and veins, remain perfectly free. The pus globules are now and then absorbed, and produce deadly effects upon the constitution; but their large size prevents this occurrence under ordinary circumstances.

The author's style of expression in general is argumentative and strictly to the purpose. His forte evidently lies in the didactic. His work, for the most part, is written in this style; but occasionally he wanders in the domain of trope and metaphor, and it is only then that we have felt uncertain as to his meaning. It is stated in the preface that "scientific men are not, and cannot be, practical," the simple converse of which proposition is, that practical men are not, and cannot be, scientific: if this be true, Dr. Williams might have saved himself the pains of his undertaking, which is avowedly for the purpose of bringing them nearer together. In S. 461 we read the distinguishing characteristics of pus globules "are their want of cohesion, and tendency to impair the consistency of fluids and textures with which they may come in contact." We were therefore not prepared to find it asserted in S. 470, "that obstruction

in the circulation of the lungs and liver, in those cases where pus has forced its way into the general circulation, results from cohesion and consolidation of the globules of pus contained in the blood." Excepting these inadvertencies, the great object proposed to be obtained by the publication of the *Principles of Medicine*, viz. to bring about a better understanding between science and practical medicine, which, as twin sisters, should proceed by one path, rendering mutual good service to each, is never lost sight of. Important practical deductions meet the eye in every page. The work will prove very useful to the medical student; and to the practitioner who is desirous of keeping pace with the knowledge of the day, and of being informed of the many important discoveries recently made in the various branches of science connected with practical medicine.

MEDICAL GAZETTE.

Friday, February 16, 1844.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tuari; potestas morbo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

METROPOLITAN MORTALITY IN 1843.

THE pen of the Registrar General has been unusually prolific during the last week. Besides the usual weekly table, now put forth in an improved form, we have been favoured with the quarterly table of provincial mortality, the annual chart of metropolitan mortality, and a fifth annual report, extending to 373 folio pages, with such a formidable display of tables, and such an array of algebraic formulæ, that mathematics must henceforth be classed among the indispensable preparatives for a medical education.

Out of this immense mass of material we have selected for present consideration the mortality of London in 1843, which will naturally lead to some reflections on the causes of the higher

rate of mortality in town than in country districts; a subject which is discussed at great length in the appendix to the Registrar General's report.

The mortality of London during the years '39-'40-'41 and '42, has been singularly steady. The numbers have been 45,441, 46,281, 45,284, 45,272, giving an annual average of 45,570. The mortality of 1843 has exceeded this average by no less than 3,004. It has advanced to 48,574, of whom 24,961 were males, and 23,613 were females. The first inquiry which naturally suggests itself out of this statement is, whether this increase is diffused equally over all the varied forms of disease by which the population of London is thinned, or whether it be confined to particular diseases, or particular classes of diseases. To determine this point, we may compare the deaths by epidemic and sporadic disorders, in the two years 1842 and 1843. In 1842, the deaths by epidemic maladies were 7696, by sporadic diseases 33,005, by old age 3346, and by violence 1225. In 1843, the deaths by epidemic maladies were 10,008, by sporadic diseases 33,907, by old age 3541, by violence 1118. It will be perceived that the difference is referrible almost entirely to the increased prevalence of the epidemic tribe of diseases, where, indeed, all great fluctuations of mortality might naturally be looked for. 2312 persons died of epidemic maladies in 1843, more than in 1842.

We have next to ascertain in which of the epidemic maladies has an increase of mortality been most conspicuous. The following table will put this matter in a very clear light.

Table of the deaths by epidemic and endemic diseases in London, in the years 1842 and 1843 respectively.

	1842.	1843.
Typhus	1174	2083
Hooping-cough	1603	1908

Scarlet Fever	1221	1867
Measles	1293	1142
Small-pox	360	438
Diarrhoea, Dysentery and Cholera	973	1160
Other zymotic disorders	1069	1119
Total	7696	10,008

This table shows that all forms of epidemic malady have been more fatal (and we may fairly presume therefore more abundant) in the year 1843, than in the preceding year, but that the difference is greatest in typhus and scarlet fever. It is curious to witness the low point which small-pox has reached, the mortality by it in each of the two years scarcely exceeding one-fourth of that by measles. Some persons are sanguine enough to ascribe this to the operation of the Vaccination Extension Act. A few years, however, will shew the hollowness of this theory. All past experience tends to prove that the period of variolous epidemy will some day return, when in all probability either typhus fever, scarlet fever, or hooping-cough, will subside into the position which small-pox now occupies.

Season has, as usual, influenced to a certain degree the amount of metropolitan mortality. The order of the seasons in 1843, in respect of mortality, has been as follows:—

Quarter ending	Zymotic maladies.	Total mortality.
December 30	2909	13,728
April 1	2971	12,312
July 1	2499	11,433
September 30	2619	11,091
Total	10,008	48,574

The difference of result which the two columns of this table indicate, shews that the law which regulates zymotic mortality differs in some degree from that which influences the intensity of other forms of severe disease in man, especially of thoracic diseases, which, in respect of season, follow the order indicated by the total mortality.

We may now pursue our comparison

of the mortality in 1843, with that of former years, through the chief varieties of sporadic disease. Encephalic disorders caused in 1843 the deaths of 7729 persons. In 1842 the numbers registered under this head were 7595; in 1841, 7560. Consumption would appear to be rather on the decline. The respective numbers are, 1841, 7326; 1842, 7145; 1843, 7104. This, however, may be owing in some degree to altered nomenclature, for we find the total amount of pulmonic diseases to have augmented. The registered numbers are, 1841, 14,177; 1842, 13,990; 1843, 14,470; and a still more striking augmentation is perceptible in the deaths by cardiac disease. The numbers entered under this head are as follows: 1841, 993; 1842, 1046; 1843, 1234.

We can have little difficulty in ascribing this difference to improved modes of diagnosis. By the way, we are happy to find that the system of requiring a medical certificate prior to registering the cause of death is now very generally pursued in the metropolis. We hope it will be ultimately (and that at no distant date) rendered imperative by act of parliament. We do not anticipate any serious objection to such an enactment, originating either with the profession or with the public.

The mortality of abdominal diseases presents no feature of peculiar interest. The uniformity of the deaths registered under the head of "teething" is perhaps worthy of note. The numbers in the three past years have been 913, 914, 955. The total mortality by this section of maladies has been in each respective year 3390, 3396, 3708. Rheumatic affections, with other diseases of external parts, have been rather more fatal in 1843. The numbers registered under this head in 1843, are 326, while in the two preceding years they had been only 251 and 280. The hetero-

geneous complaints associated by Mr. Farr as the diseases of uncertain and variable seat (including dropsy, cancer, debility, and hæmorrhage), exhibit a slight diminution upon the returns of the two preceding years. The respective numbers are, 1841, 5456; 1842, 5715; 1843, 5205. We find in this division fifty deaths laid to the door of gout. Surely these would have found a more appropriate locality in class 9. The seat of gout can hardly be viewed as less fixed than that of rheumatism.

The following is a summary of the ages at which the mortality in 1843 has taken place. There died in London

Between birth and the age of 15	23,261
Between the ages of 15 and 60	15,397
Of the age of 60 and upwards	9750
Ages not ascertained	166

Total 48,574

This mortality upon a population of 1,876,000, gives one death to every 39 persons living, or very nearly 26 in 1000. This is far from being a high rate of mortality; nevertheless it exceeds considerably the average mortality of the country districts of England. Mr. Farr, in his explanatory letter to the Registrar General (page 200, Appendix to the Report), has entered at great length into the probable causes of this phenomenon. He first enunciates the fact by the following intelligible statement. The south-western division of England comprises, in Wiltshire, Dorsetshire, Devonshire, Cornwall, and Somersetshire, a population very nearly approaching to that of the metropolis. Making a due correction for the slight difference of population, it appears that there died, in four years, 176,210 in the metropolis, to 130,298 in the country district. The excess of metropolitan deaths was, in those four years, 45,912. In other words, a greater number died in *three* years in the metropolis, than died in *four* years in the south-western counties

of England : therefore the mortality in a dense population is, to that of a scattered population, as 140 to 108. Now what are the chief agents in the production of this result ?

Mr. Farr acknowledges that we have not data sufficiently accurate to enable us to judge of the comparative incomes of the labouring population of towns and rural districts. Nevertheless, it is clear that the command over the necessities of life is not in favour of the country population, which exports annually emigrants in the prime of life to the towns in search of better wages and more comfortable subsistence. The cause, therefore, of which we are in search, does not exist here. As little chance have we, according to Mr. Farr, of finding it in the ordinary atmospheric influences, heat, moisture, cold, and dryness, which must fall very equally upon town and country districts.

Mr. Farr considers, therefore, that we are thrown upon *atmospheric impurities* as the prime agent in bringing about the comparatively great mortality of towns. He shews how the atmosphere becomes vitiated by the respiration of the two millions of beings who jostle us in London, and by the innumerable fires and lamps which blaze around us. But he lays much more stress on the smoke and other matters *suspended* in the atmosphere of cities, as leading to the increased mortality there experienced. The following extract will convey to our readers the general result of Mr. Farr's reasonings on this important topic. We can only regret that our limited space prevents us from doing more justice to the author, by quoting his opinions at greater length.

"Every population," says Mr. Farr, "throws off insensibly an atmosphere of organic matter, which hangs over cities like a light cloud, slowly spreading, driven about, dispersed by winds, washed down by showers. It is matter

which has lived, and is undergoing, by oxidation, decomposition into simpler organic elements. The exhalations from sewers, churchyards, vaults, slaughter-houses, and cesspools, commingle in this atmosphere, as polluted waters enter the Thames. In the transition to decay they become poisonous, and notwithstanding the wonderful provision of nature for the speedy oxidation of organic matter, the density of this floating poison is sufficient to impress its destructive action on the living ;—to receive and impart the processes of zymotic principles, and to connect, by a subtle, sickly, deadly medium, the people agglomerated in narrow streets and courts, down which the wind does not blow, and upon which the sun seldom shines."

"To this cause," adds Mr. Farr, "the mortality of towns is, as it appears to me, to be ascribed. The people live in an atmosphere charged with decomposing matter, of vegetable and animal origin. In towns there are fewer facilities for the sunshine to decompose it, for currents of wind to sweep it away. It is most dense in the densest districts. Its effects, therefore, disease and death, must be most evident in towns, and in the most crowded districts of towns."

This latter proposition Mr. Farr proceeds to prove, by comparing the mortality of the Whitechapel with that of the Bethnal Green district, and shewing that the mortality is much higher in the former of these districts, where the density of the population is more than double that of Bethnal Green.

That there is much ingenuity and a great deal of truth in this exposition of the sources of urban mortality we do not for a moment question ; but we think that the nature of the occupations of an urban population, and the attractions of the gin-shop, hardly meet with their due share of attention. Our space, however, does not allow a fuller investigation of the question, nor, indeed, is it needful. Our chief aim has been to lay before our readers, not our own speculations, but the deductions of Mr. Farr, whose thoughts

are constantly directed towards this subject, and whose herculean labours are incessantly devoted to the establishment of pathology upon principles as fixed as those which govern other branches of physical science.

WIDOWS AND ORPHANS OF MEDICAL MEN.

AN advertisement on the wrapper of our present Number announces the Annual Dinner of the Society for the Relief of the Widows and Orphans of Medical Men; and we most earnestly request the attention of our readers to this most excellent institution. The following brief account is taken from the preface to the little pamphlet containing a list of its members.

This Society was formed in the year 1788, by Dr. Thomas Denman, Dr. Richard Dennison, Dr. Andrew Douglas, Dr. John Sims, Dr. John Squire, Mr. William Chamberlain, and Mr. Thomas Randall, with the object of establishing a fund for the relief of those widows and orphans of deceased members who might need, and be deserving of, assistance.

It unites the advantages of a provident, with those of a benevolent society. It is provident, as the members may, through it, protect their families from destitution; and it is benevolent, as its benefits are conferred on those who are left in indigent circumstances. All duly qualified members of the profession, residing within the limits of the Society, are eligible for proposal; and the mode of admission is by ballot.

The Society's affairs are managed by a president, twelve vice-presidents, three treasurers, and twenty-four directors, who are elected by the members annually, and whose services are gratuitous.

The Society has been greatly assisted by legacies and contributions from members and others, and has especially to acknowledge the gracious patronage of various members of the Royal Family.

The permanent efficiency of the Society depends on the maintenance of a due proportion between the available income, and the claims made on the funds. Computations have been made by experienced actuaries on points susceptible of calculation by way of average.

The proportion of members whose families may become claimants for relief scarcely admits of calculation; but the experience of more than fifty years has proved the wisdom and benevolence with which the Society was planned, and the prudence and efficiency with which its affairs have been conducted.

The Society is enrolled among friendly societies; the capital stock, converted into sterling money, is invested in the Bank of England at compound interest, and amounts to more than £41,000.

77 Widows, and 124 Children, have been relieved since 1793. 31 Widows, and 24 Children, are now receiving relief, which amounts to about £1,400 per annum.

LECTURE

ON

TUMORS OF THE FEMALE BREAST,

IN CONTINUATION OF THE LAST LECTURE;
AND ON THE

ADMINISTRATION OF MERCURY IN CASES OF SYPHILIS.

*Delivered in the Theatre of St. George's
Hospital, Feb. 7, 1844,*

BY SIR BENJAMIN C. BRODIE, BART.

Tumors of the Female Breast.

GENTLEMEN,—The observations addressed to you in the last lecture were founded on the supposition that you would take care to distinguish scirrhus and other malignant tumors of the breast from those of a non-malignant character. I do not think it necessary to call your attention to the diagnosis of these different tumors, but I am desirous of impressing upon your minds that you must be careful to learn it for yourselves, from your own observation, and from other lectures. When a surgeon tells me that he has been particularly successful in the operation for scirrhus tumors of the breast, I always suspect that he has not been very accurate in his diagnosis. An acquaintance of mine once said that he had operated for scirrhus of the breast ten times, and that in no single instance had there been a return of the disease. An experienced surgeon would not have made such a statement;—and it so happened that he desired me to examine a tumor which he was going to remove, and I discovered that it was nothing more than a chronic abscess of the breast, which he denominated scirrhus.

On the Administration of Mercury in Cases of Syphilis.

I now call your attention to another subject—the administration of mercury in cases of syphilis. My object is not to enter into details, but to offer some general observations on the subject, which, at this time, when there is much difference of opinion respecting the use of mercury, and much random practice in its exhibition, may, I trust, be of some service to you when you first enter on the practice of your profession.

Mercury was employed for the cure of syphilis very soon after the disease was first recognised in Europe; I believe within three or four years after the siege of Naples, where it was formerly supposed that it first broke out. From that time to this, through good report and through evil report, in spite of the too strong prejudices of some in its favour, and of others against it, mercury has maintained its general reputation in the profession. However, at different periods, other remedies have been proposed as substitutes for it. Sir William Fordyce wrote a pamphlet to shew that syphilis might be cured by sarsaparilla; Mr. Grant, an army surgeon, alleged that it might be cured by opium; some one also asserted that ammonia would produce the same effect; and others have advocated the exhibition of nitric or nitro-muriatic acid. There have been many other such proposals, which it is not necessary to enumerate. In Spain, Portugal, the West Indies, the islands of the Pacific Ocean, and other hot climates, it is said, on what seems to be good authority, that persons recover from the venereal disease who never take a particle of mercury. Notwithstanding what I have just stated, in the beginning of this century there was a prevailing notion that mercury not only was a specific for syphilis, but that the disease could never be cured without it. Mr. Abernethy, in his work on what he calls pseudo-syphilis, lays it down as a rule that syphilis is uniformly progressive if this remedy be not administered. If a disease came before him in which the symptoms yielded without the use of mercury, he pronounced that the disease was not syphilis. It is true that he gave no reasons for this extraordinary assumption. It was a complete *petitio principii*; and this illogical conclusion has almost rendered valueless this part of his works. Not long after this opinion was published by him, and when I may indeed say that it was generally prevalent in the profession, a friend of mine, the late Mr. Rose, who was afterwards surgeon to this hospital, instituted a series of experiments on the subject of the treatment of syphilis. He had ample opportunities for conducting

them, as he was surgeon to one of the regiments of Guards. Soldiers cohabiting with the lower order of prostitutes, are, as you may suppose, very liable to become affected with syphilis. For a year or two he treated every soldier labouring under the disease that came into the regimental hospital without mercury. I saw these cases, and from time to time watched their progress with him. Every sore upon the organs of generation got well under his management. Many of them, probably, were not venereal, but of course many of them were. The hardness of the cicatrix left after a venereal sore disappeared under this mode of treatment. Some of the secondary symptoms were slight, and others were severe; in fact, exhibiting nearly the usual character; but they went away without the use of mercury. Mercury was had recourse to in only two or three cases, and there it was rendered necessary, to save the eye, in consequence of inflammation of the iris supervening. Hence Mr. Rose came to a conclusion, which these cases certainly seemed to justify, namely, that syphilis was curable without the use of mercury. Other army surgeons repeated the experiments with the same results; and I believe that the disease is even now treated in the army to a great extent on the same system.

These observations led a certain part of our profession to a view of the subject entirely different from that which had been entertained previously. They not only alleged that mercury was unnecessary for the cure of syphilis, but that it did a great deal of harm, and that the introduction of it into the system was actually worse than the disease which it was intended to cure.

With respect to the recovery from syphilis without the aid of mercury, I may observe, that it appears to me that you cannot properly apply a rule drawn from the observation of what happens in soldiers, to society in general. In all cases the effects of disease depend very much on the kind of constitution that is attacked. Students coming from the country are often astonished by the difference in recovery from compound fractures in a London hospital, and where they have seen them occur in a purer air, and in another order of persons. In London the cholera destroyed 300 out of 15,000 inhabitants; in Sunderland it carried off a very large proportion (I forget exactly what) of the population; as it did in Paris also. In London its destructive influence was felt, not among the affluent classes, but among those who were ill fed, ill clothed, and breathing a poisonous atmosphere; and these last fell victims to it with great rapidity. So I apprehend it to be with syphilis. Soldiers are persons of strong constitution, and in good health, otherwise

they would not be received into the army. They are not much advanced in life; they are taken into a regimental hospital, are kept under the constant eye of the surgeon, and are dieted exactly as he pleases. The general health is attended to in every respect; they are not allowed to be exposed to the influence of atmospheric changes; and, in short, from their constitution, and from the situation in which they are placed, it may well be supposed that they have a power of throwing off morbid poisons not enjoyed by other persons. Experience fully confirms these observations. I know that in this hospital I have tried to treat syphilitic patients without mercury with very little success indeed; and I venture to say, that in private practice the attempt to adopt this plan, as a general rule, will always be a failure. Sir William Whympy, who was surgeon-major of the Coldstream Guards, but who has now retired from the army, and who saw a great deal of syphilitic practice, told me that he could manage the cases of private soldiers in this way, but not those of the officers. Mr. Rose at first thought that he might adopt the method of treatment which he had followed in the army in private practice also, but he soon found that here it was unsuccessful, and he was forced to give mercury just like other people. In cases where he did not administer it, he found that he was continually becoming involved in difficulties.

With regard to the other notion, that mercury often tends to aggravate the disease instead of curing it, I know that its injudicious use will often produce that effect; but I am satisfied, and experience fully proves it, that it is not so with its wise and judicious administration. It has been said that diseases of the bones do not occur where mercury is not employed; and, indeed, I believe that in patients in whom mercury has been injudiciously used, disease of the bones is more frequently met with than it was in Mr. Rose's patients, in whom mercury was not had recourse to at all. I know, also, that when mercury is given for other diseases—for example, for an hepatic affection, or for diseased testicle—it will sometimes be productive of nodes afterwards; but while I admit this, I still believe that syphilis will give rise to disease of the bones, even where mercury has not been given. I will mention a well-marked case in point. A gentleman had a chancre which no one doubted to be venereal; he took no mercury, and it healed up. I forget the exact symptoms which followed, but when I saw him in consultation with Mr. Rose, a couple of years afterwards, he had extensive disease of the bones of the nose, and the disease was still going on, in spite of various remedies which he had used, and yet he had taken no

mercury. We agreed that the best thing to be done was to put him under the influence of mercury. He was to have taken lodgings in London, for the purpose of going through a course of mercurial inunction; but, in the meantime, he had a fit of epilepsy; this was succeeded by a second and a third fit. He became maniacal, and died. I do not know that his body was examined after death, but neither Mr. Rose nor myself doubted that the disease had crept up the ethmoid cells, affected the cribriform lamella of the ethmoid bone, and ultimately the brain and its membranes. I may mention another case, which also had been treated by Mr. Rose without mercury. A venereal sore healed with some simple treatment, but a few months afterwards the patient was seized with pain in the limbs, which were considered to be neuralgic. By and bye there were nodes on the shin and elbow. He had never had any disease before this chancre, and we could not but suppose that the poison had entered into the system, and that without giving rise to the first order of secondary symptoms, it had gone at once to the second order, and affected the bones. The conclusion of the case was remarkable; the patient got entirely well under the use of sarsaparilla.

Experience proves to me, and I am sure that it will prove to you also, that we have hitherto found no remedy having the same power of extinguishing the venereal poison as mercury. But then it must be judiciously administered at the time, and in such cases only as are proper for it; and without all this care it may do great harm. In this there is nothing at all remarkable, for (with the exception, perhaps, of sarsaparilla) I do not know any medicine calculated to do great good, that may not, under certain circumstances, operate as a poison. I saw a gentleman very nearly killed by an over dose of quinine; others have died in consequence of the imprudent exhibition of the iodide of potassium, and others have been killed by arsenic. A remedy that is strong enough to do good is almost invariably strong enough to do harm, if it be not properly used.

You are not, then, to suppose that you are to administer mercury at random in all cases of syphilis: but the general rule is, that it should be given; and it being so, I shall endeavour to point out briefly, not the cases in which you may exhibit it, but the exceptions to the rule as to its exhibition.

There are persons of a certain delicate constitution, having what is called a scrofulous diathesis, disposed to phthisis, and other diseases of the same class, and here you should not administer mercury till you are quite sure that it is wanted. Nevertheless, I believe that scrofulous persons, who really have syphilis, are best treated by mercury.

If mercury be to them an evil, syphilis is a still greater evil. Scrofulous diseases are more especially developed after the system has been affected with a morbid poison. Scrofulous persons disposed to phthisis will have tubercles in the lungs after scarlatina, measles, and small-pox, and it is just the same after being affected with syphilis. Enlargement of the glands of the neck often takes place where the system is disturbed by the syphilitic poison; and this shows you what may be expected as to other organs. When in these cases it is absolutely essential to exhibit mercury, it must be done with great caution; the remedy must be given in moderate doses, and the patient must be carefully watched all the time that he is using it.

Persons that appear to be in strong vigorous health are not always good subjects for mercury. There are many persons of this description who, in consequence of drinking a large quantity of wine, and other irregular habits, are in a bad state of constitution, very unfavourable to the use of mercury. It is true that the poison of syphilis in such persons often produces frightful and intractable symptoms. But, nevertheless, it is best to defer the use of mercury until the constitution has been improved, for if you administer it sooner you have to contend both with the mercury and the syphilis. If you make the patient for some time lead a more regular life, and attend to his general health in all respects, you may then resort to mercury with advantage, and probably cure the disease.

There are some individuals in whom, for some reasons which we cannot assign, mercury always operates as a poison, and you cannot tell who these individuals are until you have made the trial. This is in itself a sufficient reason why you should watch every person very carefully to whom you administer mercury, especially if he has not taken it before.

In the case of primary sores, where there is a great deal of inflammation in the neighbourhood, it is scarcely ever right to employ mercury in the first instance, for the probability is that it will cause the inflammation to terminate in sloughing. The inflammation must be combated by bleeding, purging, and other means, and it is better to patch up the sore as well as you can, and let the disease go on until it has produced secondary symptoms, rather than to exhibit mercury under the circumstances just mentioned.

In cases of phagedenic and sloughing chancre, where its condition depends on a bad state of the patient's constitution, it is always wrong to give mercury at first, for it will aggravate the disease and make it spread more rapidly. But there are cases in which

the phagedena depends on the intense action of the venereal poison; and here, as I shall explain presently, mercury may be given.

In cases of secondary symptoms, you will occasionally find that mercury, instead of acting upon and curing them, will disturb the general health, and at the same time aggravate the symptoms, and the more mercury you give the worse they will become. This arises from the patient being in a bad state of constitution, and which may depend on causes not under the control either of yourself or your patient; or it may be owing to his having taken mercury in an injudicious manner. Under these circumstances you must, for the present at least, suspend the use of mercury. The patient may appear to get well when first he leaves it off, yet he will probably subsequently require it again. To illustrate this last observation I will mention a case. A lad was brought into this hospital with a sore throat, and what appeared to be a syphilitic eruption in different parts of the body—in a state of painful ulceration. He was emaciated, and altogether looking exceedingly ill. I found that he had been taking mercury under a private practitioner, in large quantities, for not less than five months. His gums had been, and still were, exceedingly sore, and the more the mercury was pushed the worse he became. I directed him to leave off the mercury, and in its stead I gave him sarsaparilla. In a short time the eruption disappeared, and he was discharged as cured. After the lapse of a few months he came to the hospital again, with a sore throat and a return of the eruptions, having taken no mercury in the interval. I gave sarsaparilla a second time, and he got well, but the eruption did not disappear so rapidly as in the first instance. I still thought it imprudent to have recourse to mercury. After he had been away three or four months, he came to us a third time, with a recurrence of his old symptoms. I again resorted to sarsaparilla, and the eruptions yielded, but more slowly than on the previous occasions. Towards the conclusion of the time that he was in the hospital, iritis supervened, for which I gave him the oxymuriate of mercury for a short time, until the iritis had subsided. Some two or three months afterwards the disease again broke out, with nearly the same symptoms as before. Now he went into the Lock Hospital, under the care of Mr. Blair. This was fourteen months after he first came to St. George's, and he had taken no mercury, except for the iritis, during the whole of that time. Mr. Blair now, very properly, put him under a course of mercurial inunction, and I believe that he was permanently cured. If I had done this when he first came into St. George's, I should probably have killed him. I might mention a great

many cases illustrative of the same point, if it were worth while to do so.

I have said that, in the great majority of cases, mercury is the best remedy you can employ for the cure of syphilis; provided always that it be judiciously and properly administered. There are different ways of exhibiting mercury. It may be given by pills internally; it may be applied externally, in the form of ointment, or by the method of fumigation. The mercurial preparations that are given internally are various—blue pill, hydrar. c. creta, calomel and opium, Plummer's pill, iodide of mercury, bichloride of mercury, and some others.

You will find it very convenient to give it internally, in the shape of pills, when you want to affect the system rapidly, as, for example, in the case of iritis. A patient labouring under iritis is in danger of becoming blind, and you must put him under the influence of mercury as soon as possible; and this is better accomplished by giving calomel and opium than by using mercurial friction. In slighter cases of syphilis the disease may be cured very well by mercury exhibited internally. There are some patients so circumstanced that they cannot take it in any other manner; because they are living with their families, and for other reasons. Altogether, there are a great many instances in which it is either convenient or necessary to exhibit mercury internally. But if you ask me which is the best way of using mercury where the symptoms of syphilis are not of the very mildest character, I must say that that by inunction is infinitely to be preferred. Mercurial inunction is dirty, laborious, and troublesome, and it makes the matter public to the family in which the patient lives; hence it will generally be unpleasant to him; but it has these advantages:—it is much less liable to gripe or purge; it cures the disease a great deal better, and does not damage the constitution half so much as mercury taken by the mouth; nay, I will go so far as to say, that, except in the slighter forms of the disease, you really cannot depend upon any other kind of mercurial treatment for the production of a cure. You may patch up the disease by giving the remedy internally, but it will return over and over again, and then you may cure it at last by a good course of mercurial ointment properly rubbed in. The patient, if not well instructed, will perhaps continue the friction for a few minutes, but the friction should be continued before a fire at first for at least three quarters of an hour. After some time the ointment will enter the system more readily, and it may then be rubbed in for a shorter period. Where the symptoms are not of a mild character, the patient should, if possible, be confined to the house,

except perhaps for an hour or two in a fine day. The going out into the fresh air (as Mr. Pearson observed long ago) will undo the effect of the mercury. You never can be responsible for thoroughly eradicating the disease where the patient is at all exposed to cold or wet, nor where he does not lead a most regular and careful life in all respects.

In all cases where you employ mercury, remember that you are to have two objects in view—first, to cure the present symptoms, and secondly, to prevent a return of the disease. It seems to me that a great number of practitioners at the present day keep in view only the first object, and lose sight of the second. I have frequently seen a person who has taken mercury for a chancre, which has, perhaps, healed in a fortnight, then leaving it off, although a very hard cicatrix has been left. Under such circumstances, in nine cases out of ten there will be secondary symptoms. If mercury be taken for the primary symptoms, the patient should never leave it off till the hard cicatrix has disappeared; nor, indeed, for some time afterwards. And so, with regard to secondary symptoms, it should be continued for a long time after they have disappeared. A man has an eruption of the body: it disappears, under the use of mercury, in the course of a month, but the remedy must be used as a prophylactic for another month. I should say, that if a patient be confined to his house, or only allowed to go out a little in a fine day, and if he be made properly to rub in the ointment, and the course be carefully watched and continued for some time after the symptoms have subsided, you will, in the great majority of cases, make a real and permanent cure of the disease. This is not, I fear, the way in which it is administered by the majority of practitioners now, but it was so administered formerly. You must not suppose that we have advanced alike in all departments of surgery; indeed I am sure that in some things we have gone back, and I believe this to be one of them. I am much mistaken if the mercurial treatment of syphilis, as employed by the late Mr. Pearson during the greater part of his life, was not as nearly perfect as possible. At any rate, it was much more successful than the less careful treatment of modern practitioners. That gentleman was surgeon to the Lock Hospital, and having no general hospital to attend to, the powers of his mind were more especially devoted to the study of syphilis and its treatment; and the practice which I have now recommended was that which he usually adopted. I had an opportunity of meeting him a great deal in private practice, when I was young in my profession, and I am satisfied that his practice was eminently successful. In a work of his, on the articles of the materia medica recommended for the cure

of syphilis, in which there are many excellent observations on the use of mercury, he enters into details in a way in which it is not my intention to do at present. I refer you to his work.

I will take this opportunity of stating a class of cases in which you may employ mercurial inunction with the greatest advantage. Children are sometimes born with syphilis—the father or mother having been affected with it. The child looks thin, and is of small size, and instead of thriving becomes thinner and thinner. At the end of three weeks it is covered by a red scaly eruption; there are aphthæ in the mouth, chaps about the lips and the anus. Where this combination of symptoms exists, you may conclude that the child is affected with syphilis. I have tried various ways of treating such cases. I have given the grey powder internally to the child, or some kind of mercury to the wet nurse. But the mercury given to the infant by the mouth gripes and purges severely: that given to the wet nurse cannot be depended on; and at all events the latter is a very cruel and scarcely justifiable practice. The mode in which I have treated such cases for some years past is this: I have had a flannel roller, on one end of which I have spread some mercurial ointment—say a drachm or more: I have applied the roller thus prepared round the knee, and repeated the application daily. The child kicks about, and the entire being thin the mercury easily enters the system. This causes neither griping nor purging; in a child it does not even in general cause soreness of the gums, but it cures the disease. I have adopted this practice in a great many cases with the most signal success. Very few of those children recover in whom the mercury has been given internally, but I have not seen a single case in which this method of treatment has failed.

Mercurial inunction may be employed in certain cases in which mercury taken internally would absolutely do the greatest harm. For example, a gentleman had a phallogenic sore upon the penis. It could not be said that he was in ill health before, and therefore there was reason to believe that the disease was spreading, from the intense influence of the venereal poison. He took calomel and opium; the gums became tender; but the sore became worse than before, spreading more rapidly: the greater part of the glans was destroyed. The disease shewed no disposition to stop, and resisted all modes of treatment, until at last he was put on a course of mercurial inunction, when the progress of the ulceration was at once arrested, and the sore healed as fast as possible. I have seen several cases of the same kind.

Another mode of employing mercury is by fumigation. It may be applied locally—

to a part; or generally—to the whole person. In the latter case the patient is placed in an apparatus like that used for sulphur fumigation, but instead of sulphur the black oxide of mercury is thrown upon the hot iron. If you wish the system to be affected as speedily as possible, this may be accomplished by his holding his head in the inside of the bath for two or three minutes, and inspiring the mercurial vapour. I have used this with success in several cases where it was my object at once to affect the system, but I have found that Mr. Pearson's objection to it is very well founded—namely, that it is difficult in this way to regulate the action of the mercury. You may affect the system too much, or too little; and you may be taken unawares by the patient's gums becoming all at once excessively sore. With respect to the effect of mercury on the system generally, I may observe, that you cannot thoroughly depend upon it as an anti-syphilitic remedy, unless the gums be made rather sore, and there be some degree of salivation.

But, as I have already stated, there are cases in which mercury is not proper at all, and in which there are reasons for doing without it, either altogether, or for a time. In some individuals, in private practice, as well as among soldiers, by mere attention to the general health, the disease will be thrown off. A gentleman had a well-marked venereal eruption. He was in London, and was going to take mercury, but was called into the country, and I therefore advised him to defer it for the present. Shortly after being in the country, and under the influence of a purer air, all the symptoms vanished. Similar cases are recorded in Mr. Abernethy's book, and he, as I have already mentioned, concludes (somewhat hastily) that the disease was not syphilitic. After a mercurial course it is not sufficient to let your patient go, and say your disease is at an end. It is very important that he should be kept in good health. There are many persons in whom the disease is never so thoroughly eradicated but that, if the health be broken down, it may shew itself again a considerable time afterwards. It is always well, after a long mercurial course, to put the patient through a course of sarsaparilla, with a view to remove the debilitating effects which the mercury itself produces on the constitution. I will mention a case, to shew how much depends on the state of the general health. A gentleman had secondary symptoms: I put him through a course of mercurial inunction, and for ten weeks he was altogether confined to his house and most carefully attended to. He took mercury for some weeks after the eruption had disappeared. Appearing to be quite well, he went to Lisbon, and continued well. But at the end of a year he took cold, which was followed by a severe

attack of erysipelas. A practitioner whom he consulted very indiscreetly bled him to a large extent. An enormous abscess formed, and between the erysipelas, the abscess, and the loss of blood, his health became completely broken down. While in this state he had a return of the venereal disease, the symptoms being of a more severe character than formerly. An English surgeon, resident at Lisbon, put him under a course of mercury, and cured him. In cases where symptoms are aggravated by the use of mercury, they may often be removed by sarsaparilla; and in other cases they will subside under the use of the iodide of potassium. It is very much the custom now to administer the latter remedy in cases of syphilis; and no doubt, in some instances, it is productive of very good effects. It comes in very well where you have reasons for not giving mercury; but if you ask me whether you can rely upon it as you can upon mercury, I say, "Certainly not." You may remove slight symptoms by giving it in small doses for a long time; and more severe symptoms, by exhibiting it in larger doses; but in the latter cases, so far as I have seen, it does not make a permanent cure, and the symptoms return even under the use of the remedy. As a prophylactic, iodine is not to be compared with mercury, although it may be taken under certain circumstances with the greatest advantage.

I have spoken of the necessity of administering mercury, not only till the symptoms are relieved, but for a considerable time afterwards. But you may ask, whether a long course of mercury is not more likely to injure the constitution than a short one? Undoubtedly it is; and that is the very reason why you should prefer a long course. I will explain what I mean. If the course be a short one, the disease is sure to return; you have then to repeat it, and again the disease reappears. Thus you have repeated courses; and not only is the system weakened by the mercury itself, but the venereal disease, whenever it does return, assumes a more formidable character than before. But if, on the other hand, you put the patient through a long course in the first instance, such a frequent recurrence to the use of mercury will be unnecessary. A patient who takes mercury for a chancre, for a month or five weeks, may probably never want it again; but if it be taken only for a fortnight, he has secondary symptoms, and then it will be required for at least six weeks, perhaps for ten; so that that which is a short course at first becomes a long one in the end.

With these observations I conclude the course of lectures which I undertook to give during the winter. But before we part, allow me to make a few observations with respect to the lectures themselves.

When I resigned my office of surgeon to this hospital, some three or four years ago, I could not but recollect that it was here that I had been able to lay the foundation of what little knowledge I possess of my profession. I also remembered that some of the happiest hours of my life had been passed within the walls of this institution, in friendly intercourse with my pupils; and that among the latter I had found some of my sincerest and kindest friends. Altogether I felt that I owed a debt of gratitude to St. George's Hospital and the school attached to it; and it was my wish, as far as I could, to do something towards discharging this debt. Under this impression, I offered to the Weekly Board, and to the medical officers, to give this annual course of lectures.

I have endeavoured to give you some information which, however little its value may be to those experienced in surgery, will, I hope, be of use to you, who are younger men. But I had another object in view. The lectures, as you may have perceived, have been entirely practical, and have been drawn from scarcely any other source than my own observation and experience. I wished to give you an example of what your own mode of study ought to be. In these times there is a great quantity of medical literature, such as it is. There are books on specific diseases, dictionaries, cyclopædias, compendiums, pocket-books of all kinds, and nothing is more easy than for a person who has a tolerable memory to look into books and learn by rote the prevalent doctrines and opinions of the day, and then to be able to discourse on these subjects as if he really understood something of them, and pass what is called a good examination—that is, answering the questions put to him to the satisfaction of his examiners. But depend upon it, this will be of no use to you hereafter. A man who is contented with getting up this sort of knowledge is, in practice, absolutely good for nothing. He goes to a patient's bed-side, but not knowing anything of disease practically, he is in doubt respecting the treatment which he should have recourse to, and he has not that confidence in himself which will enable him to take the heavy responsibility, which, as a medical practitioner, he ought to take, in difficult cases. You must, in order to be qualified for the situations you are to fill in life hereafter, gain your knowledge, not from books, but from your own observations and investigations. I do not say that you are not to look at books, and to read them, but you should do so only in conjunction with practice. If you have a particular case before you, refer to a good book, and that will enable you to examine the case far better than you would otherwise do; but the principal thing is to observe symptoms

and the operation of remedies for yourselves. The same rule applies to anatomy, to surgery, and to physic. You may get up anatomy by being examined by your teachers, and by conning over compendiums, and you may appear a very good anatomist when you go up for examination; but anatomical knowledge is of no avail in practice unless you have acquired it by studying the parts in the lecture-room, and examining them for yourselves, and with your own hands, in the dissecting-room. A person who has acquired anatomy in any other way will find that he has no chance whatever when he comes in competition with one who has made himself an anatomist by dissection. And I repeat that it is the same with respect to hospital practice: you must study the cases, and observe them for yourselves. Examine them in the morning, refer to your books, or notes, in the evening, and reflect on the observations which have dropped from the medical officers. Take notes with your own hands; no person can learn medicine or surgery who does not do so. It is the only way to obtain the real practical information.

I take the liberty of making these observations, not that you particularly need them, but believing that they may be useful to all younger persons in our profession. Be assured that the mode which I have pointed out is the only one by which you will be enabled to succeed in the exercise of your profession with comfort to yourselves, or advantage to the public. In fact, I think that very few will get any practice at all who pursue their studies in a less legitimate manner. I say all this with the most entire feelings of friendship, and influenced by an earnest desire that you may be successful in your undertakings, and do honour to the school in which you have received your education.

NOTE FROM DR. LYNCH.

To the Editor of the Medical Gazette.

SIR,

As the letter of Sir Benjamin Brodie, which you inserted last week, implies a charge against me of misrepresentation, I beg to give the following reasons for making the public statement, that he had described the great body of general practitioners as a subordinate class:—

1. That he is reported in the *Lancet*, at that period the only record of medical affairs, to have used it at a meeting of hospital surgeons.

2. The charge is repeated at page 215 of the first volume of that work for the year 1829, in a letter from a correspondent.

3. That the assertion was repeated on several occasions in the editorial comments of the *Lancet* and other journals, without any attempt to deny or to refute it.

4. That he frequently used the terms higher and lower grade in his evidence before the select committee of the House of Commons.

5. The charter itself which he then propounded, and since succeeded in effectuating, contains all the invidious distinctions that degrade the members who were before *equal*, and create a body of Fellows without any fixed standard of qualification, or without reference to age, station, attainment, or utility; and thus, as a necessary consequence, all the members not belonging to the Fellows are placed in the category involved in the answer to the question 5723 of the same inquiry, beginning thus—"Would the members of your proposed lower grade," &c. &c.

6. Because all those who practise midwifery—the most useful, the most indispensable, and frequently the most difficult branch of medicine, requiring knowledge, skill, and great manual dexterity—are deemed unworthy of a seat in the Council of the College of Surgeons! On this silly pretext nine-tenths of the members, to whom the maintenance and restoration of the health of the great majority of the people of these realms are intrusted, are made a subordinate or lower class.

I leave to the philology of the learned and ingenious baronet the choice between the two terms. For my part, I consider "lower grade" to be the more offensive.

I am, sir,

Your obedient servant,

JORDAN ROCHE LYNCH,
M.D. M.R.C.S.L.

Feb. 6, 1844.

[We have given insertion to the above from a desire to be impartial; but we trust the matter may now be considered as at an end.—ED. GAZ.]

ACNE INDURATA.

To the Editor of the Medical Gazette.

SIR,

I SHALL feel obliged if you, or any of your numerous readers, will, through the medium of your valuable journal, inform me the best and most successful treatment of acne indurata. In the obstinate case that urges this request, the digestive organs are healthy. Lotions of hydrocyanic acid, bi-chloride of mercury, and borax, have failed.

I remain, sir,

Your obedient servant,

A CONSTANT READER.

Feb. 6, 1844.

JUDICIAL ADVICE TO MEDICAL PRACTITIONERS

"In the course of a case which was tried at the Old Bailey yesterday, a medical witness in giving his evidence used the word 'tume-faction,' upon which Mr. Justice Coleridge said, 'I suppose by tumefaction you mean swelling.' Witness—'Yes, my lord.' Mr. Justice Coleridge—'Then it would be much better to use plain English, than to speak that sort of mongrel Latin.'" Such is the purport of a paragraph in the *Times* of Wednesday, or rather such is the paragraph itself. Now we must say, that, if correctly reported, Mr. Justice Coleridge was most absurdly hypercritical; we deny that "tume-faction" is mongrel Latin, or even a pedantic expression, and we think it rather too good that the lawyer should think of correcting the doctor for a fault which the world at large regard as *par excellence* the foible of the gentlemen of the long robe.

EMPLOYMENT OF CHLORIDE OF ZINC IN TOOTHACHE.

By DR. STANELLI.

ACCORDING to Dr. Stanelli, the chloride of zinc, liquified by exposure to the air, possesses the property of calming dental pains.

His mode of application is most simple. By means of a small hair pencil, a small quantity of it is applied to the cavity of the painful tooth, and in the space of a few minutes it appeases the most acute sufferings, without causing any irritation.

Before proceeding to the application, it is indispensable carefully to surround with cotton wadding, and, when the chloride has been applied, to well fill the cavity with this same cotton. The mouth is finally washed with a little warm water.

The author affirms that he has obtained uniform success from this means in more than fifty cases, and that he has never observed the progress of the caries rendered more active by it.—*Annali Universali de Medicina; and Chemist.*

RHEUMATISM IN THE HORSE.

M. TESSIN remarks that M. Bouley, one of the most experienced veterinary surgeons in Paris, assures him that the ordinary course of rheumatic inflammation in the Horse is the reverse of what is usually the case in the human subject. In the latter, as all know, the affection of the joints is primary, and that of the pleura, pericardium, or other internal part, is consecutive, or secondary; whereas, in the former, pleuritis is generally the primary, and the arthritis the secondary affection.—*Veterinarian.*

THE HUNTERIAN ORATION

Was delivered before the members of the Hunterian Society, on Tuesday last, by Mr. John Hilton, being the twenty-fifth anniversary. It was our intention to have given it in the present number, but its length obliges us to postpone it until our next.

BOOKS RECEIVED FOR REVIEW.

Two Essays on the Diseases of the Spine: 1. On Angular Curvature of the Spine and its Treatment. 2. On the Treatment of Lateral Curvature by Gravitation, Lateral Exercise, &c. By R. A. Stafford, Fellow of the Royal College of Surgeons of England, &c. &c.

Elements of Physiology, for the Use of Students, and with especial reference to the wants of Practitioners. By Rudolph Wagner, M.D. Translated from the German, with Additions, by Robert Willis, M.D. Part III. On Sensation and Motion.

A Manual of Pharmacy for the Student of Veterinary Medicine; containing the Substances employed at the Royal Veterinary College, with an attempt at their Classification, and the Pharmacopœia of that institution. By W. J. T. Morton, Lecturer on Veterinary Materia Medica, &c.

ORATION

DELIVERED BEFORE THE
MEMBERS OF THE HUNTERIAN
SOCIETY.

At the 25th Anniversary,

BY JOHN HILTON, Esq. F.R.S.

Lecturer on Descriptive and Pathological
Anatomy, Guy's Hospital.

MR. PRESIDENT AND GENTLEMEN,

It has often been remarked, that when a stranger enters St. Peter's, at Rome, for the first time, the immediate impression is one of disappointment; the building looks smaller than he expected to find it. So it may be said of the first sight of mountains; their summits never seem so near the clouds as we expected to find them.

But a closer acquaintance with these, and with other grand and beautiful objects, convinces us that our first impression arose, not from a want of greatness in what we saw, but from a want of comprehensiveness in ourselves to grasp it.

What we saw was not all that existed, but all our untaught glance could master; as we know it better it remains the same, but we rise more nearly to its level; our greater admiration is, indeed, but the proof that we are become able to appreciate it more truly.

Something of this kind, modified into adaptation, will exemplify what have been my feelings regarding myself and the Hunterian Oration; such was my early misconception of what I had promised, that whilst I was a looker-on through the vista of a twelvemonth, it seemed, at that distance, simple, easy, unimposing, and almost unassuming, to engage to prepare a short discourse.

As I had been journeying on the circle of the last year, and so brought nearer to the object, divested of the long shadow of a

coming event, I obtained a more exact view of what I had voluntarily undertaken.

I confess myself chilled and embarrassed by its nearer approximation, and by its importance; and although attracted by the aspect it wore, I was indisposed, until compelled by stern necessity, to enter upon its details. Thus far, the analogy was faithful to the oration, and impressively true to myself.

As I became better acquainted with its intended comprehensiveness, and the necessity for its completion, through the rigid and unvarying admonition of time, I am compelled to admit, that whilst I found myself quite equal to a proper appreciation of my difficulties, I felt equally certain that I was not rising more to their level. I could not, by any diversion, or temporary interpretation, induce myself to praise an undertaking the fulfilling of which I had so much and so justly admired from the lips of my predecessors.

With such harbinger of my result, I would most willingly have turned away from its contemplation, had I not been restrained by a sense of what was due to the Hunterian Society and my own consistency.

The public records of this Society do not furnish or provide any direction for the character or subject of the annual Hunterian Oration; this probably intentional omission of its earliest proposers and advisers left me no alternative but to select some considerations, not aspiring to novelties, but to which I thought I could draw attention, with a slight hope of their being not altogether unprofitable to some members, by bringing before them facts in advance of days gone by, or by reminding them of what may have been displaced from their stock of memory by fading time, or added occupation; and in the further hope that those others, whose high attainments and extended experience have rendered them distinguished and lustrous ornaments of our profession, and this Society, might be induced to receive

them with solicited indulgence, without feeling that they have sanctioned any thing unworthy their presence, or that they have done more than sacrifice their time in aid of the Society's established custom, and added a required encouragement to a good intention on the part of one of their associates.

The name of this, the Hunterian Society, gives the first claim to the memory of a man now more than half a century the child of history, but whom, nevertheless, be deemed, by reflection, the parent of this Society. For although its archives do not hold his autograph, it adopted his name as its leading feature; it received from him, through those taught by his former pupils, its earliest members, the impulse of existence, the fruitful seed of that character for sound practical observation, for proper appreciation of facts, and love of truth, which continue to uphold it conspicuously in a community redolent with talent and accumulating intelligence.

To the Hunterian Professor at the Royal College of Surgeons belongs, essentially and specifically, the completion of another portrait of John Hunter: upon him will devolve, to-morrow, the reanimation of his mundane existence, the tracing from his birth the gradual development of his character and acquirements.

It will be for him to shew the influences of education, and natural predilection, on his career; to examine the means and appliances which he made serviceable; to raise up, in high and bold relief, the superstructure of his active mind; to place before his audience the immediate consequences, the progress, and the results of his doings; to lay open, expose, and place in their proper light for transmission or reflection, the features and expression of a life whose extent of benefit to his profession, and real good to mankind, is yet, notwithstanding the many good and safe deliveries, within the womb of time.

But, Sir, looking upon John Hunter as our peculiar guiding-star, and admitting the influence of his ascendancy over our proceedings, I cannot avoid taking a transitory telescopic view of him, and the light he shed over the sphere of his occupation.

To John Hunter belonged an untiring energy, which thwarts procrastination or forgetfulness; he had inherent in his nature an enduring perseverance worthy the object, and equal to the destination he had planned for it.

If we refer to his course of varied pursuits, we are compelled to admire the zeal and indomitable industry which he employed to lay the foundation for that splendid and unique museum which now shines forth bright with science, and radiant from its Hunterian nucleus.

Hunter dwelt and communed with nature

all the days of his professional life; he watched her proceedings with an earnest anxiety to explore her deep recesses, and to understand her emanations. He became the companion, but the humble servant, of nature, following her, with gentleness and respect, through many of her infinite windings and mazes, noting with admiration the succession of her proceedings, and thence denoting honestly his own opinion of her laws, or what seemed to him to be the impelling, the guiding force: thus he became the translator of the book of nature, and his eye could detect design and beauty where the atrabilious sceptic beheld nothing but confusion and deformity. His mind contained the most estimable and enviable power of ascending, by self-acquirement, from particular facts to that broad generalization which has given him a just claim to human originality, by the establishment of fundamental principles.

By his elaboration and legitimate influence, a large number of facts, in which, before, order and connexion did not appear at all, or appeared by partial and contradictory glimpses, were brought into a point of view in which these properties of order and connexion became their essential character. By him it was shown, that a contributing fact, although dislocated, was but the manifestation of the same principle, and that each particular was what it was by virtue of the same original impression: thus by him the inscription was decyphered, the truth enunciated.

His was not the refinement of a pre-meditated or specially adapted education. We may discover in his writings that he did not possess that exactness in the use of words which leads to the most precise expression; his was not that instinctive, harmonious, glowing language, which would express less if uttered more. Indeed, we cannot deny that some of his ideas are invested with much obscurity.

With his facts perhaps recently acquired we may see the rapid flow of reasoning flooding over, or breaking down, its natural bounds; his super-imposed inferences, full of expanding truth, seem to oscillate and tremble when tried against the weight of true induction.

His literary compositions may be indistinct by their fulness, and dark with abundant meaning: they have been accused of incomprehensiveness, yet, as a whole, they have withstood the swelling conflux of time and opposing circumstances.

Some of his opinions and conclusions freely promulgated, perhaps too freely, deduced as from nature, rude in form—hence not her transcript—these, nurtured by nature's self, and to us immature, have remained nearly inviolate, and will doubtless

continue for the mental plenitude of successive generations, to ponder and dwell upon as sacred veiled truths—

“Like words

That leave upon the still susceptible sense
A message undelivered—till the mind
Awakes to apprehensiveness, and takes it.”

Hunter's reputation was not of that parasitical character so often witnessed, and of which he himself became subsequently the support; he was the sturdy oak, he was not the ivy: he laid the basis of his own elevation; he saw himself raised up into acknowledged superiority by the development and growth of those germs he himself had planted and cultivated. When he discovered himself placed in that proud and isolated position, which proclaimed him, by almost general consent, the regenerator of his art, we see no poisoned weapons cast down upon his jealous or aspiring contemporaries, no unmeasured vanity for himself, no contempt for others. How striking and pleasing in this respect does the contrast appear in the expressions of Hunter and Paracelsus, each in his zenith, each addressing introductory remarks to a course of lectures to his own pupils.

Hunter says, “I do not mean that all I say in this course will be new, that none of the opinions and observations which I shall deliver are to be found in any publications; but many of my ideas, and the arrangement of my subject, are new; and consequently my terms become in part new.”

Paracelsus lived when a bald head and a long beard were considered as wisdom and intellectual: I think he must have taken as his prototype, Zoilus of old, the pretending critic of Homer and Plato, who always kept his head close shaved, believing that the hairs of his head would have acted as so many suckers, drawing away the nourishment from his chin, and by that means have starved his underhanging, and, in his opinion, his understanding, beard.

But to Paracelsus:—He exclaims, “I would have you to understand, that the meanest hair on my head knows more than all your writers put together; the very buckles on my shoes are more learned than your Galen and Avicenna, and my beard has more experience than all your academies; nor is the hour far distant when I shall see the swine pulling my opponents through the mud.” No wonder he was proud of his beard, that he could sing his own praises so well, and was disgusted with swine; for at three years old he is said to have been made an eunuch by a sow.

Hunter was not successful as a public teacher: why was this? May we not apply for Hunter the reasoning employed by Socrates under similar circumstances? Socrates, who was the son of a midwife,

used to say, “that as my mother, although she is very skilful in her profession, cannot deliver a woman unless she be first with child; so neither can I raise knowledge out of a mind where nature has not planted it. It is true Hunter did not attract a *large number* of congenial minds; but he taught and directed Home, Baillie, Wilson, Chevalier, Abernethy, Carlisle, Coleman, Macartney, Astley Cooper. *Each* of these was *himself* a host.

Hunter aimed at final truths, which only meditation can discover, and only experience recognize. His was an ascendancy, the fruits of a life of accumulation. His opinions may fall; but his facts are immutable, imperishable; they belong, not to years nor to ages, but to all time, and stand secure,

“Like some tall rock, whose bare broad bosom
Towers from the earth, and braves the inclement
sky,
In conscious pride, its huge gigantic form
Surveys imperious, and defies the storm.”

He has left a name which must be held in praiseworthy remembrance by the whole world, but especially by his countrymen, so long as honourable industry and integrity shall be considered virtues—so long as contributions to science, and the benefit of mankind, continue passports to distinction and fame—so long as a proper sense of humanity has a place in the human heart.

Leaving the further consideration of Hunter to the appointed authority at the College of Surgeons, I wish to remind you of one of the several means which appears to me to have been made largely available in raising our profession so near to the character of a science.

We have in our times, hydropathy, homœopathy, neuro-pneumatism, neuro-magnetism, mesmerism, and other doubtful, if not *untrue-isms*, lashing propriety and common sense with loud and precocious display: we may hear—

“These partial spirits now aloud complain,
Think themselves injured that they cannot reign;
And own no liberty but where they may,
Without control, upon their patients prey.”

To the biography of science, these hypotheses will appear only as so many names gilded by fashion (that unwholesome arbiter of right) with gaudy and meretricious colours; they add nothing to the science of our profession, nor will they append any thing permanent to the basis of our principles of practice; they are the dissolving views of the day.

Sixty years ago, Dr. William Hunter, a man of deep thought, and great foresight, in one of his lectures says, “Were I to guess at the most probable future improvements in physic, I should say, that they would arise from a more general and more accurate examination of diseases after death. And

were I to place a man of proper talents in the direct road for becoming truly great in his profession, I would choose a good practical anatomist, and put him into a large hospital to attend the sick, and dissect the dead."

Such was the opinion of one of the most distinguished men of his day; and we cannot but remark, how curiously true and prophetic it has been, as regards the source and means of elevation adopted by all the truly great in our profession since that time, and I should say also, of the steady and certain improvements in our knowledge of disease.

But, gentlemen, let me divest your patience of any thing like alarm. It is far from my intention to attempt the placing before you the accumulation of opinions and facts convergent to the present period of professional acquirement.

Our profession may now be considered a compound of science and art; yet we must acknowledge, as a science, it is very imperfect; and daily experience compels us to admit, that, as an art, it is most difficult and perplexing.

In all ages we may discover many authors, who publish their opinions, if, for no less worthy object, certainly for the purpose of obtaining experience and practice.

Others, the true benefactors to the profession and to the community, write their experience for its own sake; from an honest belief and conviction of its intrinsic merit, as a worthy contribution to the existing stock of knowledge.

If you would desire to see, and to appreciate, the value of facts in pathological anatomy, look to the mass of books of our profession, brought to light during the early part of the last century, and compare them with those which bring us to our present period.

With few (but most honourable) exceptions, you will find the former occupied with dogmatical language, replete with conflicting uncertainties, the leaves covered with presumptive and grandiloquently expressed opinions; whilst those of the later date (but also with some very striking and much to be regretted exceptions), will be found teeming with pathological facts, well observed, and properly associated with symptoms during life, based therefore on physiology, with opinions promulgated as fair deductions from them.

If you admit this simple and plain proposition, that diseases are to be understood and treated according to their nature, and not in reference to their names alone, you at the same time, and by the same expression, acknowledge the value and importance of morbid anatomy.

The full admission and completion of this proposition has led to the very just opinion,

that a great part of the successful treatment of disease depends upon the clear discrimination of disease.

In the practice, at least in the honest practice, of our profession, the first thing to be done is, to ascertain if possible the *actual nature*, not merely the symptoms of the disease presented for our opinion.

A professional man ought to endeavour to answer severely and satisfactorily, this self interrogation—Am I certain of the nature of this disease, the cause of the symptoms?

If the reply be satisfactory, I need only appeal to your recollections, to remind you of the agreeable confidence you obtain in your subsequent plans of treatment.

I have no hesitation in stating my conviction, that too many of the profession treat the symptoms, and omit the other considerations as to cause.

There are others, who, from want of time or habit, or from other unintelligible influences, do not even take the trouble to analyse the symptoms, so as to elucidate their origination; or, to separate those which belong to the predominant disease from those which may be accidental, without any necessary association with the disease to be treated.

Symptoms of disease are only the expression of suffering, or uneasiness on the part of the organ or organs diseased.

Symptoms are, *if properly appreciated*, the external demonstration of internal derangement; and we know by experience, that they may exhibit themselves at the seat of the disease, or somewhat removed from it.

Patients judge of their disease by the symptoms; we ought to judge of the symptoms, by the disease, by the cause, by the pathological anatomy of the symptoms.

I suppose we must on reflection arrive at this conclusion—that the laws of animal organization, of health, and normal function, have been the same from their first existence. Nor can I suppose it will be doubted, that the symptoms of the *same disease* have been always *the same*. The same symptoms have constantly presented themselves for observation, soliciting prehension from successive generations: why were they not understood? why never properly appreciated, nor attached to structure?

I think it will be admitted, that one of the great, if not the greatest of the contributing causes, towards elucidating diseases, and dragging them, by the weight of facts and by the force of reason, from the contracted thralldom of nosology or nomenclature, and towards fixing the principles of the practice of medicine and surgery on a sound broad basis, may be found essentially in the more exact observations on the results of disease—their pathological anatomy.

In the practice of medicine, the greatest assistance has been derived from the study

of morbid anatomy, associated with symptoms.

What has led to the extraordinary and astounding precision, now so frequently presented to us by some of the profession, in distinguishing, locating, and treating diseases of the chest. It may be replied, auscultation; but a moment's reflection will convince us, that, without the confirmation, the crowning mark of pathological anatomy, it could not have proved any thing. Auscultation has only given you additional means of exploring, it gives you the symptoms; morbid anatomy explains to you the cause of the symptoms.

The pathological anatomy of the lungs encourages the hope in all of us, and to many gives the proof, of the curability of many cases, formerly grouped under the unstructural and indiscriminating denomination of phthisis.

Post-mortem evidence has separated the heat of pneumonia from idiopathic fever; and although it has done little towards stating what fever is, it has done much towards proving what it is not; namely, that it is not, as we were desired by the would-be authorities to believe, an uniform, recognizable, structural lesion.

Post-mortem examinations have demonstrated that many diseases of the chest depend upon the want of due relation between the capacity of the lungs for aerating the blood, and the size of the organ for circulation; that these organs become cause and effect to each other's diseases: to be in perfect health, they ought to be in perfect equilibrium.

The more frequent causes of very sudden death are now proved to be at the heart, and not in the brain, as formerly supposed; the symptom is the same, it is apoplexy still. It was always cerebral, it is now generally cardiac.

The secretion of air by serous membranes will be proved to be a mere supposition, growing out of imperfect examinations after death.—How many causes has morbid anatomy enabled us to discover for dropsy, formerly classed as a disease, now admitted to be only a symptom?—By what means have we arrived at our present knowledge of the immediate and the remote effects of renal disease, with its modifying influence upon other local or general affections, if not by morbid anatomy?—Whence will be derived the truth, which is now gradually evolving itself, whether coagulable urine may depend upon other lesions, with or without disease of the kidney? I say, morbid anatomy, in a great measure. I believe more careful observation after death will shew us that internal hæmorrhage, by exudation or transudation, is at most a very rare occurrence,

and that hæmorrhage from the nose, hæmoptysis, hæmatemesis, hæmorrhage from the bowels, and hæmaturia, are local defined lesions, ruptures or ulcerations, very small, but discoverable by care and perseverance.

It appears to me very difficult to imagine or to understand that local condition of blood-vessels which will allow general exudation or transudation of blood through their parietes at thousands of points at the same time. If it were from congestion, the very circumstance of the blood escaping at one point would prevent a further escape, by taking off distension.

On the other hand, several cases of internal hæmorrhage, which would, with the ordinary routine at post-mortem examinations, have been put down as from exudations, I have myself proved to have been caused by very small ulcerations, not larger than the head of a pin, or by the rupture of a very small blood-vessel.

From examination after death, of cases observed during life, I am confident that some of the cases of chronic rheumatism, and those cases which are known by the obscuring titles of chronic rheumatic affections, are, much more frequently than is supposed, diseases of the nerves; and, I may add, that the cause of such symptoms is very often discoverable, by tracing the anatomical associations of the nerves of the part.

When we inquire into our actual and positive knowledge concerning the diseases of the nervous system, the different opinions and prevailing uncertainties, which are daily witnessed concerning the same case, offer any thing but a very favourable indication; yet, upon a retrospective view, we are very far in advance of our predecessors; an improvement depending very much upon an improved pathological anatomy—the more accurate association of disease to symptoms.

We are yet deficient in that precision, as to cause of symptoms, which I have mentioned as now so ostensible in diseases of the heart and lungs. Many causes contribute to this: an incapability of positive discrimination as to the cause of nervous function, or of making any just comparison between it and physical agents with the properties of which we may be familiar; a want of *very* accurate observation and notation of symptoms during life; defect on the part of the necroscopist in detecting disease with accuracy, when indicated only by slight changes in colour and in consistency, or in properly attaching either or both of these evidences to their true causes, whether *ante* or *post mortem*, &c. &c.; these, and many other real and important considerations, in reference to the ages of the patients examined, might be mentioned. What geography is to the truth of history.

anatomy is to practical medicine and surgery. Our first and great imperfection in the nervous system is due to our deficiency in the anatomy of the brain and spinal marrow. It is at present unsatisfactory to the best anatomists.

I think I need only remind many whom I have the honour to address, of those halcyon days of study at *alua mater*, *dura mater*, and *pia mater*; of the lobes, of the different corporate bodies, thalami, hippocampi, tения, fornix, eminences and depressions, septa and surfaces, columns and commissures, glands, and admitted dark places, &c. &c. which were then found in the brain, to obtain their acknowledgment that the anatomy of the brain required improvement and more certainty.

If I advert to the large and more recent foreign importation of unmeaning anatomical nomenclature, I apprehend it will be confessed there is yet much to be done towards exposing and elucidating the real structure. Look, for example, at that colony of new names now located on about an inch of the cerebellum, including, literally, a valley, its flocks, its fissures, its specific and little hills, three commissures, two pyramids, a tongue with wings, a spigot, a nodule, a uvula, an almond-like body, &c. &c. These, and other names, have got possession of this unhappy valley; but I hope not a fixity of tenure. I think I shall, after this enumeration, gain the admission that there are but few competent to examine this organ with due minuteness, and a full appreciation of appearances.

It is consoling to know that there have been, and are still, worthy labourers in this field of inquiry. Some may, by too hasty conclusions, be gathering unripe fruit; and putting it by most surely to spoil and decay. There are others who, after clearing away much of the fulness of rank vegetation, and who, availing themselves also of the prepared ground, have sown, and are sowing, seed, which may be slow in growth, requiring much irrigation of industry and talents, and many genial minds, before it ripens into fruit, yet it will assuredly become fit to be gathered, and time must disclose who shall be the reapers.

The sphere of surgery admits the full importance of pathological anatomy. Scarpa says, the brilliant progress which surgery has made in modern times is only the result of pathological anatomy; that is, of exact comparisons of the natural state of our organs, with their different diseases; and that it is from the same source that the most rational curative means with which modern surgery is enriched are deduced, as so many corollaries—methods to which we are indebted for the perfection of operations.

The surgeon, before he commences an operation, likes to feel assured of the exact nature of the disease. Before he makes his incision, he reflects on the changes of relation, of form, of texture, of appearance, which may have been induced in the part by disease. To appreciate these he must refer to morbid anatomy.

Pathological anatomy suggested to John Hunter the right treatment of aneurism; to Dupuytren, the cure of artificial anus; to Scarpa, it explained the cause of hæmorrhage after operation for inguinal hernia. How much has been accomplished by it, in reference to diseases of the joints, in our days, in defining the character, in locating the seat of the diseases, and in identifying them structurally; thus leading to more successful modifications in the plans of treatment. But I am satisfied we have not yet approached the confines of the maximum of benefit to be derived from treatment of joint diseases. An amputation is but the admission of inability to cure a disease; the higher praise rests in the successfully avoiding the mutilation; and many limbs, which formerly would have been amputated, are now cured. Excision of joints accrues from observing that the disease is frequently, nay very generally, confined to the immediate neighbourhood,—a fact ascertained by morbid anatomy, and its consequences not yet carried out to their fullest extent.

How many emasculations are now avoided by a more exact observation and recognition of the diseases of the testicle. A few years ago, it was a common thing to see the testicle removed; now, however, in consequence of our more accurate information as to the character of its diseases, cases are so successfully treated without the knife, that an amputation of the testicle has become a comparatively rare operation.

Look at what was accomplished through pathological anatomy, associated with symptoms during life, by the energetic mind and able hands of Sir Astley Cooper: his works on hernia, diseases of the breast, and testicle, replete with sterling merit, bespeak the results. The community experiences the advantages, the benefits, of his researches.

Recent pathological investigations have shewn surgeons that ultimate success, in most operations, depends more on the proper selection of cases, and their subsequent treatment, than upon the completion, or immediate effect, of the operation itself. The causes of death, after operations, are generally concealed in visceral disease. Death seldom happens from the operation itself; and pathological anatomy, or post-mortem evidence, points distinctly to the kidneys, the lungs, and the liver, as the organs

which most frequently determine the fatal issue; need I do more than ask you to consider how many important suggestions arise out of this evidence. How many deformities are now remedied by acting upon the pre-acquired necroscopic fact, that a distorted joint is not necessarily a diseased joint, but a secondary effect of contracted muscles? What has led to that diversity and inequality of opinion, now discoverable, as to the propriety of the operation for strabismus—an operation, which has added much to our usefulness, and so added another laurel to the profession, by enabling many persons to see their way, in this world, better and straighter than before? But time has shewn, as connected with this operation, that there are many persons who have a right to complain of that sudden ebullition of professional anxiety to improve the appearance of mankind, which induced some surgeons to seek after, and solicit, this operation, and by which patients were led to submit to it. These patients have suffered from that pre-voyance of success and reputation which led those peculiarly philanthropical operators to believe they could mesmerise, and annihilate for ever, by the touch of the knife, every species of visual obliquity.

Why has this operation disappointed so many of its admirers and advocates? It results, in my opinion, in a great measure, from the treatment being directed solely against the symptoms, without reverting to the causes of that want of harmony of action, and of that deficient equipollence, which may have induced the obliquity.

It may be adduced, as another of the advantages to accrue from the study of morbid anatomy, which points out the causes of strabismus, as numerous, differing, and various, and requiring not an uniform, but a discriminative, and an adaptive treatment.

As regards the operation most recently before the profession and the public—that of removing ovarian tumors. The propriety of the attempt originates in the pathological facts, that ovarian disease is often a simple cyst; that even when malignant, continues for a very long time an isolated disease; that the surrounding structure may remain unimplicated in the same disease for several years, although the ovarian tumor itself may be far advanced.

But this is an operation which is very likely to be thrust back again into obscurity, if not by other more legitimate and natural means, certainly by its over zealous advocates, who do not take into due consideration the varieties of ovarian disease, its varying associations with different periods of life, and numerous other contingencies.

There are those, who now look upon this as a fixed and settled operation, as an operation justifiable, by having already a proportion

of success as great, to the whole number, as other important operations. Applying statistics, where they appear to me to be most inapplicable, namely, to the determining the treatment of disease, I would remind those who employ the statistical reasoning as their oracle, that it necessitates that every case, unsuccessful, as well as successful, shall have been published, which may not be the case.

To apply the numerical method to this, or any other operation, it infers that every case shall be known to the person who is to draw the inference: it ought to infer also that all the cases were sufficiently alike to be grouped together. Suppose these, and a number of other considerations, granted, and brought by the numerical enthusiast to determine in his mind the propriety of an operation, any result at which he may arrive can only apply to that which is past; it cannot, by any fine drawing, or by any distortion, be made to influence any *certainly* as regards the very next case which may present itself. That will be a fatal or successful case, obviously independent of any thing which may have preceded it. Each case must be treated on its own intrinsic merit.

To make statistics available in the prospective treatment of disease, you ought to have, what it is impossible to obtain, the definite number to calculate from, perfect similarity throughout, in those cases already past, and a complete certainty of an exact correspondence in all the cases to come. It is to my mind a fallacy, to treat practically, medical or surgical cases, or to attempt to determine the propriety of any operation by statistical inferences alone: the inferences may look well on paper, but they are too much on the surface of cause and effect to add any thing satisfactory towards a right and safe conclusion.

As well might the cosmologist, for the purpose of instruction, expect to ascertain the exact position and relative quantity of earth and water composing the globe, by cutting out, with the greatest diligence and extremest nicety, the different portions of each from a map. He would know nothing of the depths of the rivers, or the heights of the mountains; nor would he, by such means, make himself acquainted with those treacherous shoals and quick sands buried in the restless ocean, but ever ready to engulf the unwary; nor could he indicate those death-striking upheaved rocks, or coral reefs, which lie submerged in the wild waste of waters, and become the great danger to secure and safe navigation.

Our general monitor will not allow me to do anything like justice to the conclusive evidence which pathological examinations present, of the unintentional but fatal in-

juries inflicted upon patients by the empirical, unscientific, force-employing treatment, of stricture of the urethra.

Many persons think that a little blood lost during or after the passage of the catheter, for retention of urine, or of the sound, for the cure of stricture, is of no importance, nay, rather beneficial. The introduction of the sound or catheter, to be harmless, ought to be bloodless; and every drop which escapes is the mark of undue force.

I wish I could induce those persons who compete with stricture of the urethra, *vi et armis*, to think, and reflect a little, upon what they are doing, when, as they term it, they are trying to overcome a stricture, and lastly succeed; not by going through the stricture, but by tunnelling the walls of the urethra.

To those, who, in spite of all obstacles, will always succeed, or will never fail or be foiled in passing a catheter, when prompted more by personal vanity than by the *necessity or emergency of the case*, I would say, beware of producing a state of things certain to eventuate in those incidents of mischief which every man ought to try to avert; and which must be deeply lamented by those who have contributed to their occurrence, when unavailing, and beyond the reach of remedy.

To those who persevere in bringing about such direful results, and who cannot, or will not, hear the still small voice of reproving conscience, let me urge upon them the solicitations of pure humanity, which begs for more gentleness from their hands.

These are a very few small fragments, from the great mass of daily acquirement, which I have thought right to detach, for your consideration; and although they have been most imperfectly displayed, I hope they carry with them the evidence of some of the advantages to be derived from the study of pathological anatomy associated with symptoms during life.

But in pathological investigations we must not be satisfied, or think our task completed and concluded, with a minute examination of the solid products of disease, however carefully displayed by the scalpel of the most expert dissector. If we resolve to ascertain the origin of the minute changes which structures have undergone in disease, or the causes of the more obscure and general affections, and to fix with human certainty the constitutional treatment of disease, we must carry our inquiries into the preceding agent or pathogenesis. We must solicit, with patience and endurance, more exact information regarding the functions of the nervous system, the healthy and unhealthy constitution of the blood, and other animal fluids. The study of molecular changes in structure, and of the alterations taking place

in the animal fluids, is but a more refined species of anatomy.

The mechanical process of the scalpel being here inadequate, the microscope, and the exact process of analytical chemistry, are to be made available in detecting minute variations in the solids and fluids, which must otherwise have escaped our notice. But to the still inquiring mind it is obvious, that, although morbid anatomy, thus carried out, may be the cause of the symptoms of a disease, it will show us only the changes which fluids or solids have undergone—the results of an antecedent agent, the effects of abnormal action, produced during life by and through matter under the influence of vital endowments: and here I would remind you, we have reached or gone beyond the limits of certainty, and we must invoke to our aid, as a means of comprehension, general physiology, or our imperfect knowledge of the laws of organized and living bodies.

The inquirer into such ulterior investigations has to deal with the complex properties of matter in their most complicated form; matter whose composition surpasses his intelligence, matter which the chemist may be capable of analysing to a very minute degree, even to what may be to him its constituent ultimate elements, yet, notwithstanding the tremendous progress made in animal chemistry, he (the chemist) must admit that he wants the chemical proof by synthesis—that his science is perfectly inadequate to the reformation, or reproduction, of any of the organised solids or fluids. It is, in fact, matter interwoven with the properties of unsubstantial life, held together and controlled by a law known only to the Law-giver. If the most astute mind should attempt by experiment, or the microscope, the search for first causes, the genesis, when he imagines himself actually at the focal point of his long and arduous observation, at the moment he invests himself with the hope, and probably the belief, that he is at the very threshold of the hidden truth, the vital principle which contains the solution of his difficulties baffles him; collecting all his mental vigour, and art-full appliances, he strives, as it were, to seize the wished-for treasure by force. But, alas! the human energy which he employs, and the transient violence which he uses, defeat themselves, and the body dies, that it may preserve the secret of its life—known only to Him whose extent of knowledge is infinite.

Those theorists who maintain most strenuously the possibility of tracing the phenomena of life to the influence of physical or chemical agents, are constantly obliged to suppose a mode of agency altogether different from any yet known in physics or chemistry, and so, unconsciously, allow, what no efforts can avoid or conceal, the vast but inscrutable chasm between chemical and vital affinities

—between mechanical and vital forces. Into this unfathomable depth our science has, as yet, cast no ray of light, nor reason caught sight of any general law by which it may securely hold. Human science, conscious of its own insufficiency, stands aloof, in mute admiration of that rule of action by which development, assimilation, and secretion, are made the living manifestations. Notwithstanding this impassable boundary formed by an element inappreciable to our senses, it is within the sphere of human intellects, by the aid of inferences drawn from experiment and observation on appropriate facts, so to construct a science which, necessarily imperfect, susceptible of constant improvement—hence a continuing stimulus to mental exertion—may, by the process of induction, be made capable of identifying and indicating sound principles competent to direct the judgment.

In conclusion, I must add, there seems to be a law wisely prefixed for our improvement, that after the phenomena of life shall have quitted their temporary habitation on earth, the physical signs of previous disease should remain for a period almost stationary. Would it not have been as easy for Omnipotence to have converted the material body into thin invisible air at the same instant with its death, as to have created it? Must it not, then, have been preordained that a certain, but undefined, time shall intervene between the full development of those chemical laws and affinities which regulate, *by slow degrees*, the disposition of inanimate or dead matter. It is from the dead body we are to draw our first principles. We can reflect upon the superaddition of life to matter, and, by reasoning upon it as if endowed with life, *hope to come to right conclusions*. When we approach the consideration of life itself, or the spirit, we are self-restrained by our finite reason. All is darkness to the human understanding. We know not how the union was produced at first, nor do we know how it happens that the blow which prostrates the body, and imprisons it in the grave, gives pinions to the soaring spirit, crowning it with freedom and triumph. We believe the soul is destined to live

“Unhurt amidst the war of elements,
The wreck of matter, and the crush of worlds.”

But, gentlemen, these are mysteries locked up in the omniscience of the Creator. They are as inscrutable to the sage as to the savage—alike to the philosopher and the uninitiated. They are left, and no doubt purposely, to make us set only a right value upon all human science; and, while they form the groundwork of man's future happiness, forcibly point to him, that his proper and legitimate path to it is, through the gate of humility.

ON

DIFFERENT FORMS OF GRANULAR DISEASE OF THE KIDNEY.

BY J. D. HEATON, M.D.

[Continued from page 645.]

(For the London Medical Gazette.)

JOHN SMITH, age 44, admitted under Dr. Thompson, June 30, 1841; a married man, by occupation a brass turner; of middle stature, and stout conformation, having a pale sallow complexion and bloated appearance. An habitual gin drinker for many years; at one period taking as much as a pint and a half of gin per diem. Latterly he has not drunk to so great excess.

He has been under Dr. Thompson's care more than once previously for dropsy, in connection with albuminous urine. The last time he was in this hospital was in September, 1840; he was dismissed cured of the dropsy, but the urine still containing albumen. For some time after this he remained apparently well, except that his feet were occasionally oedematous, and he has passed an unusually large quantity of clear pale urine.

A month ago he was attacked with violent headache and sickness; the face became much swollen, and the whole body was soon dropsical. (This is likewise the way in which his former attacks of illness commenced.) The urine became very scanty. He had no pain in the loins, but lost strength very much. Before admission to the hospital he had taken some hydragogue pills, and had been cupped in the loins.

When admitted, the subcutaneous cellular tissue in all parts was oedematous, and there was much fluid in the large serous cavities, producing in the chest very distinct rægophony. The skin in most parts was tender and uneasy from the distension. He had no headache at this time, but seemed languid and generally very drowsy. His appetite was pretty good. He had much thirst. Tongue thickly furred; bowels much purged by medicines previously taken; urine scanty, (about lb. j. in twenty-four hours), pale, limpid, slightly acid, throwing down a copious flocculent deposit of albumen on adding nitric acid or applying heat. Specific gravity 1015. Pulse 80, full and hard; skin dry.

E brachio mitte sanguinis $\bar{x}xj$.

R Hydrarg. Proto-Chloridi, gr. iij.; Opii, gr. j. M. ft. pil. post venæsect. sumenda.

Cras mane sumat Haust. Nigrum.

The next day the coagulum of the blood which had been drawn was firmly contracted, and much buffed and cupped; the serum

was very lactescent; it had a specific gravity of 1025. The pulse still retained its character of hardness and fulness, the urine was not in any way altered, and other symptoms remained much as before.

He was ordered to take a grain of calomel, with one grain and a half of pulv. digitalis, every eight hours, and a mixture consisting of the infusion of diosma crenata with a little nitrate of potash. Also, to be bled again to 16 ounces.

The blood drawn presented the same characters as before. The pulse became smaller, but still hard and resisting. Other symptoms not altered.

On the 6th July he first complained of a severe pain in the loins. The urine still pale and copious, and very albuminous, having a specific gravity of 1015. The body universally anasarcaous. The patient very drowsy constantly. No appetite; much thirst; tongue thickly furred. Gums affected by the mercury. Pulse hard and resisting.

Omitte pilulas. Perstet in usu misturæ, et adde Tr. Digitalis ℞. sing. dos.

E lumbis ope cucurbit. cruent. mitte sanguinis ℥xx.

The cupping relieved the pain in the loins, but the symptoms seemed generally to be becoming more unfavourable. On the 7th, the abdomen was so much distended that paracentesis became necessary: about six quarts of fluid were evacuated, very gelatinous, and forming a soft coagulum as it cooled, which was subsequently re-dissolved. The patient was constantly in a state of drowsiness approaching stupor. The urine highly albuminous. From this time till death the symptoms presented little variety. The last few days of his existence were passed in a state of constant stupor, from which he was not easily aroused; but the evacuations were never passed unconsciously. The urine was not suppressed, though scanty, and remained albuminous to the last. The wounds formed by venesection and tapping (which was performed a second time) shewed no tendency to heal, but formed large sores, discharging a thin acrid matter, excoriating the surface around.

He died on the evening of the 28th.

The body was examined 33 hours after death.

On opening the thorax, a large quantity of yellow serum escaped: there were no inflammatory appearances of the serous membrane. The lungs were much congested, and discharged much serum when incised, but crepitated when compressed. There was no tubercular lesion in either lung, but there was much cretaceous matter, and black melanotic deposit, in the bronchial glands at the root of the left lung, and

of melanotic matter simply on the left side. The pericardium contained about an ounce of serum. The heart was free from disease.

The abdomen was filled with serum. The peritoneum appeared healthy. The liver was slightly enlarged: the whole surface was of a very dark lead colour, probably the effect of some cadaveric exudation of sulphuretted hydrogen, as the discoloration was quite superficial. A section of the liver presented a rather paler and more yellow colour than natural: the substance was more hard and friable than usual. The spleen had the same discoloration of the surface as the liver, but appeared healthy in other respects. The kidneys were rather smaller than natural, the right kidney being rather the larger; both presented the same appearances. On stripping off the investing membrane, the surface appeared very uneven, but not distinctly granular; it was unusually pale, being of a dirty cream colour, speckled with numerous small dark grey spots. On the convex margin of each were a few rather large flat vesicles, containing a dirty brown fluid. The colour of the surface extended through the substance of the kidney; a few black spots were seen on the section. The cortical and medullary parts seemed to preserve their natural proportions; each seemed to be pervaded by an albuminous deposit, superseding in a great measure the healthy structure, apparently devoid of vascularity, on which depended their want of the natural colour; but there was little appearance of granulation. The right kidney weighed 4 oz. 6 dr.; the left, 4 oz.

The brain presented some opacity of the arachnoid, and softening of the optic thalami and corpora striata. The arteries were free from disease.

This is a good illustration of the ordinary progress of a fatal case of albuminuria, uncomplicated by other diseases, and free from many affections frequently associated with, though not essential to the malady in question.

It is very probable that the disease took its origin from the habits of intemperance to which the subject of it had long been prone. The regular progress of the disease, though it does not render the case less valuable, presents little opportunity for comment. The attack which ended fatally was the last of numerous exacerbations of a disease which had been slowly progressing for a length of time. From the period of his admission the symptoms were so serious, that a fatal result was anticipated. The bloodless but sallow complexion shewed a great diminution of the red globules of the blood, which is one important consequence of this disease. The constant presence of albumen in the urine clearly established the true nature of the malady. The dropsy was the most

ostensible and distressing of the symptoms, and that one which, some years ago, would alone have attracted attention. The very hard full character of the pulse was peculiar, and suggested the frequent depletions which were practised. But neither this nor any other treatment at all stayed the progress of this attack, though others had been benefited by similar means. The last few days of the patient's life presented that oppression of the senses and stupefaction which most frequently precedes death in this disease.

The only additional circumstance which seems to demand remark, previously to the post-mortem examination, is the appearances presented by the blood. The firm, strongly contracted crassamentum, with its buffy coat, might seem to imply an active inflammatory state of some organ. But the clot was unusually small, even taking into consideration its firm contraction; and both these, which are the usual appearances of the blood in this disease, may be well explained by a circumstance to which we have already alluded, viz. the great reduction of the number of blood globules, which, being less abundantly interspersed amongst the fibrine of the clot, explains its diminished size, and, at the same time, allows it to contract more forcibly, so as to render the clot more firm, and give it the cupped and buffed appearance usual in inflammatory diseases.

The examination after death shewed, as might have been expected from the symptoms during life, that the kidneys were the principal seat of disease. These organs were exsanguine, from the morbid deposit which gradually takes place of the natural vascular structure; they were somewhat contracted, though not to any great extent. The granular appearance was less distinctly marked than is usual; but there could be no doubt as to the true nature of the disease, for the other appearances of these organs, as well as the symptoms during life, were all those of granular kidneys. The numerous black spots interspersed in the substance of the kidney seemed to be a punctiform melanotic deposit; and, taken in connection with a similar deposit in the lungs, in larger quantity, might imply a tendency to disease of this nature. The black discoloration of the liver was so superficial, as more to resemble a stain than a morbid structure; but the paleness of its substance, with increased fragility and somewhat enlarged size, seemed to depend on a morbid albuminous deposit, similar in nature probably to cirrhosis in this organ, or to the granular degeneration itself of the kidney.

In other instances, besides the one under consideration, we have found more or less softening of the brain in connection with granular degeneration of the kidney; but

whether this is to be regarded as more than a merely accidental coincidence, we are unable to determine.

ADDITIONAL REMARKS

ON

SUPPRESSION OF URINE.

By J. C. HALL, M.D. &c. &c. &c.

(For the Medical Gazette.)

IN his very interesting paper on this singular disease, Dr. T. Thompson remarks—"In a considerable proportion of instances, as in those described by Sir H. Hallford (Essays and Orations), Dr. J. C. Hall, and others, death has occurred within three days from the commencement of the suppression." On turning to the case recorded by me in the MEDICAL GAZETTE,* and also in my recent work†, I find that the patient recovered, after the suppression of urine had continued forty-two hours: in the majority of cases, however, coma and death take place in from three to five days. It becomes a question of some interest to discover the greatest length of time a patient has survived with a complete suppression of this fluid; for be it remembered, there is a marked difference between those cases in which no urine is secreted, and those in which the discharge is not altogether wanting. "Here there is a great difference in the hazard of a patient's situation, whether the kidneys separate a very little urine, or none at all:"‡ in the first case he gradually recovers, in the second very rarely. In Dr. Thompson's case the state of the brain was not examined, but in a case recorded by Dr. Elliotson, a man was attacked with anuria attended by hemiplegia, and that drowsiness which is always present after this disease has existed for some time, and which leads us to infer—that is to say, the apoplectic symptoms ushering in death—the urine is re-secreted into the ventricles of the brain, but in the case at present before us "nothing of the kind was discovered; there was not only no urine in the head, but no excess of fluid, either in or upon the brain: that was a result for which we were not prepared."||

† Clinical Remarks, &c. &c. p. 186.

‡ Dr. Baillie.

|| Principles and Practice of Medicine, p. 1119.

The right kidney in Dr. Thompson's case was enlarged, and "Dr. Daniell thought he could detect a slight degree of mottling."* Dr. Bright remarks, "that in cases of granular degeneration of the kidneys total suppression of urine but seldom occurs." We, however, must conclude, that various states of the system, both in health and also in disease, have an effect on the secretion of this fluid, which appears to contain elements, the longer continuance of which in the blood than natural, always produces disease, and the total suppression of their elimination death, the last hours of the patient's life being attended by symptoms denoting some affection of the brain. I quite agree with Dr. Thompson in thinking the evidence of the transference of the urinary secretion in some cases sufficiently suspicious to render it necessary to examine it with care, and to receive many of these wonderful stories with caution. In addition to the cases of Nysten Valisneri, and Marangoni†, to which allusion is made, Dr. Parr mentions a case where no urine was made for six weeks‡, and Haller quotes an instance in which it was said no urine was made for twenty-two weeks. But the truth of this last case may fairly be doubted, for Haller does not give it on his own authority, but on that of some other person§, and it is folly to suppose that the constituent principles of so important a secretion as the urine can long remain in the system without the greatest danger. Dr. Mason Good remarks, "the outlet at which these are separated and discharged is not always apparent, and hence they appear not to be separated at all." If, however, a practical and accurate pathologist make the examination, the vicarious channel will frequently be detected. In Dr. Parr's case, there was a profuse sweat; in Dr. Richardson's, the patient laboured under constant diarrhoea. A case is recorded by Dr. Arnold, of a girl, who had retention of urine for two years, and through whose skin a fluid like urine escaped; and on one occasion, when the catheter was not used for many hours, a fluid like urine was discharged from the right ear, first in

drops, and then in a larger quantity*. It appears perfectly clear, in some few cases where no urine was secreted, and in others where the fluid was retained, that patients have vomited a fluid bearing the taste, smell, and all the other qualities of urine; and others have passed it, as in Dr. Parr's case, by perspiration. It is reasonable to conclude with Dr. Elliotson, "that in the latter case the fluid has been absorbed and re-secreted, and in the former case it has been secreted originally, and has not been absorbed at all."†

Respiratory and intestinal exhalations, as well as cutaneous transpiration, exert a marked influence on the secretion from the kidneys; in fever, in small-pox, malignant cholera, after accidents and surgical operations, we have more or less (as the case may be), a diminution of the secretion of urine. When my remarks were printed in the *MEDICAL GAZETTE* four years ago, on this disease, Sir B. C. Brodie favoured me with a note, which I venture to quote, as it abounds with that sound practical information for which the lectures and writings of this distinguished surgeon are so remarkable. "I have read your paper on the suppression of the secretion of urine with much interest: in the great majority of cases of this kind I have seen, there has been some obstruction to the flow of urine, and it is curious to remark how a calculus blocking up one ureter, or a tumor pressing on one ureter, will sometimes stop the secretion of urine in both kidneys. In one case there was a very large prostate, which probably closed the orifices of the ureter, but the body was not examined after death. In another case there was a medullary fungus of the mucous membrane of the bladder, producing this effect. I had a patient with enlarged prostate, which prevented his emptying the bladder. For some time he had not secreted more than half a pint of urine daily, but the secretion was trebled on the catheter being used two or three times daily."

I recorded a case in the *MEDICAL GAZETTE* some time ago, which I attended with my much respected friends,

Messrs. Carruck and Pollock, of Kensington, in 1837. When I saw this lady, October 1st, the urine was fetid, and of a dark colour, often containing long strings of blood: she complained of "great pain in the loins," and could obtain little rest, night or day. These symptoms continued until the last five or six days of her existence, when the urine, which had daily diminished in quantity, ceased to be secreted; none was passed, nor did the catheter detect any in the bladder. Twelve hours after death I assisted Mr. Pollock in the post-mortem examination: we found extensive disease of both kidneys, particularly the right, which was one fungoid mass.

The effects of a suppression of urine consist in a declining energy and growing torpitude, clearly proving that the brain is directly weakened, and rendered incapable of supplying nervous energy. Mr. Campbell remarks, "it is not difficult to account for these effects, as they naturally follow from the blood being charged with that excess of azote which it is the office of the urine to carry off."* I may here remark to the student, that suppression of urine may be either functional or arise from some organic disease of the gland itself: the constitutional symptoms, however, do not vary in either case, and according to my experience death takes place precisely in the same manner.

The cases, however, to which I more particularly, at present, wish to refer, are those in which, independent of any derangement that is apparent in the structure of the kidneys, their secreting office is completely suspended. This peculiar condition constitutes the disease to which Dr. Willis has given the name of anuria, said by him to terminate in coma in four or five days, and in death in a few days more. I am, however, of opinion, that, as a general rule (of course, as in Dr. T. Thompson's case, there are a few exceptions), death takes place in a much shorter period; that is to say, in cases where no urine is secreted by the kidneys, and no other organ furnishes an outlet for it. Dr. Elliotson mentions a case where urine was vomited; in

another, he continues, "I saw it pass from the skin, particularly the palms of the hands." Dr. W. H. Carter mentions some cases* in which the patients were relieved by vomiting a fluid resembling urine in colour, yet altogether void of urinous smell or taste. Dr. T. Thompson remarks, in the interesting paper in the *MEDICAL GAZETTE*, to which reference has already been made, "In the present example, no urinous odour was detected in the matters discharged; and, as a general rule, in cases of ischuria, it does not appear that vomiting and diarrhoea have averted or retarded the occurrence of coma." With every deference to the opinion of this gentleman, I am inclined to think the cases already quoted from the *Cyclopædia of Practical Medicine*, as well as the cases mentioned by Dr. Richardson and Dr. Parr, lead to a different conclusion; nor can I agree with him in thinking, "we have no conclusive evidence of the transference of the urinary secretion." One of the most singular cases of vicarious discharge is that quoted by Sennectus, from Platerus, of a girl, thirteen years of age, in whom the secretion of the kidneys was compensated by a very copious flow of serous fluid from the right ear, which continued during several days†. (The Editor of the *Medico-Chirurgical Review*† mentions a case which fell under his own observation; in this case it was quite impossible to practise deceit; the catheter was passed every day, but only a few drops of blood followed. There was no affection of the head, nor is any mention made of increased perspiration or diarrhoea.) Still, I cannot help thinking with Dr. Carter, "a more critical examination in all these cases would have led to the discovery that some urine was passed—it may have been a very small quantity—but that some urine was secreted or passed," or, at any rate, that the system was relieved by some other outlet; for after the case mentioned as seen by Dr. S. Arnold, and the observations of Dr. Elliotson—"I know instances where urine has been vomited; I saw a case where it passed from the skin"—it is quite impossible to doubt the truth of these cases, which prove the transference

* *Lancet*, 1840. I may also refer the reader to the very interesting experiments of M. C. Chossat, who has endeavoured to determine whether the blood of persons labouring under anuria be loaded with azote.

* *Cyclopædia of Practical Medicine*, p. 892.

† *The Medicina Practica* of Sennectus, lib. iii. c. 10.

‡ 1833.

of the urinary secretion. In some cases of ischuria renalis a very strong urinous smell is perceptible before death, which clearly proves an attempt of nature to convert the exhalants of the skin into a substitute for the palsied kidneys, but without complete success. Speaking of the cases of Dr. Parr, Dr. Richardson, and others, Dr. Carter remarks, "If it be conceived that in these cases not a drop of urine was passed by the natural channel, or discharged at any foreign outlet; if, in a word, it be conceived that no urine whatever was secreted, might not a more accurate investigation have determined them to belong to the ischuria suppleta of Sauvages?" "It may be proper, in this place," continues the same writer, "to say a few words respecting this latter variety of ischuria renalis, in which the want of the secretion in the kidneys is compensated by a vicarious discharge, as also of that variety in which urine itself is thrown off by some foreign outlet. Cases of either description are uncommon; and, among those which have been published, some, perhaps, have been simulated; yet a sufficient number, distinctly related, and by writers of good authority, remain to entitle the ischuria suppleta of Sauvages, and the paruria erratica of Dr. Good, to our consideration*.

With regard to the duration of the disease before death takes place.—I now speak of complete suppression of urine†, for, as Sir Henry Hallford observes, a very small quantity of urine is sufficient for the exigencies of the constitution: in the case recorded by him (in the Med. Trans. Vol. VI.), the man died in about two days. Mr. Campbell's case died in little more than twenty-four hours; he found him feeding his cattle the day he was called to see him—the next he was dead. Dr. Carter states, "death takes place about

the second or third day from the commencement of the suppression. In the case I recorded (MEDICAL GAZETTE, 1840) of J. Lambert, under game-keeper to the Earl Spencer*, no urine was secreted for forty-two hours (not one drop, as was proved by the repeated introduction of the catheter); and I am not aware of any case in which a patient has recovered when the disease has continued longer than this, and when symptoms denoting an affection of the brain were present. Dr. Elliotson mentions a case attended by the late Sir A. Cooper, and two others by "a friend," in which recovery took place, but the duration of the disease is not mentioned, nor the treatment.

In our treatment of this disease, our utmost efforts to rouse the kidneys to renewed action often fail; we must, however, endeavour to relieve both the vessels of the brain, and also of the kidneys (which, in idiopathic suppression of urine, are probably congested), by general bleeding when the patient can bear it, or, when less plethoric, by cupping; the abstraction of blood should be followed by a brisk purgative, the internal exhibition of cantharides and diuretics, the application of a large blister to the loins, and an enema of oil of turpentine and castor-oil. In all cases the warm bath is, as Dr. T. Thompson well remarks, useful; it is a disease, of all others, requiring the most prompt and energetic measures: in a case of life and death no time is to be lost.

Grove Street, East Retford.

CASES OF DROPSICAL OVARIA

REMOVED BY THE LARGE ABDOMINAL
SECTION.

By D. HENRY WALNE, Surgeon.

(For the Medical Gazette.)

IT has already been made known to the readers of the MEDICAL GAZETTE that an operation performed by me subsequently to my published cases, in which I removed a diseased ovarium, was followed by a fatal result, the only

* Page 192—*ισχουρία*, a suppression or retention of urine, from *ισχω*, to withhold or retain, and *ουρον*, the urine.

† Let us keep in mind that the generic term ischuria has been employed by medical writers in general, and also by professed nosologists, to designate two very different affections. Ischuria has been termed by Sagar "retention or suppression of urine secreted by the kidneys, or suppression of the secretion in the kidneys." Sauvages uses the term, retention; Cullen, that of suppression only, both evidently regarding suppression and retention as equivalent terms. Dr. Mason Good applies to suppression the term "paruria inops"; to retention of urine, the name of "paruria retentionis renalis."

* I saw this man last week; he is in good health, is the father of three children since the attack, and has had no return of the disease.

case of the kind that has occurred in my practice. The details were communicated still earlier to the same medical society at the meetings of which I had brought forward my first and second cases, but where I had not deemed it necessary to mention my third and most complete instance of success. To great numbers of medical men, including, I believe, every gentleman who, since its occurrence, has done me the honour personally to consult me regarding such complaints as these operations are intended to relieve, I have also given the leading particulars; and it now only remains for me to put them permanently on record in somewhat fuller detail. Through the same channels it has been made known that I have used the preliminary or tentative incision, on an occasion where extensive adhesions precluded the removal of the tumor. Before proceeding, therefore, to narrate my fourth case of removal of dropsical ovaria by the large abdominal section, I will relate the circumstances of that in which I tested the usefulness of the tentative incision; a measure which I introduced in my first operation, which I have since uniformly had recourse to, and of which other operators have, by adopting it, shewn their appreciation.

Mrs. S. H., of Poplar, aged 54 years, applied to me, July 31st, 1843, in a state of great distension from ovarian dropsy. She was the mother of five children, the youngest of them fourteen years old; the catamenia had ceased thirteen years. Her disease was supposed to have existed about four years, that time having nearly elapsed since she first noticed an increase of size, and felt a soreness of the lower part, on the left side and front of the abdomen, though she never experienced acute pain from her complaint. In December 1842, she had been tapped at one of the hospitals, and a few days after my first seeing her, viz., on the 3d of August, 1843, finding her state intolerable, she was again tapped. No very remarkable circumstances, I believe, attended or followed these operations. The liquid removed was stated to be yellowish, and like white of egg in consistence. On the 22d of August, she visited me; said she was filling very fast; felt weak, but otherwise pretty well, and had a good appetite; her complexion rather yellow; the left leg

somewhat œdematous, and the right also a little swollen, but less so than the other. Her dimensions were 38 inches in circumference, and $14\frac{1}{2}$ inches from scrob. cord. to pubes. The tumor, with fluctuation, rose considerably above the umbilicus.

By Sept. 5th, her dimensions had increased to $41\frac{1}{2}$ inches in circumference, and 19 inches in the other direction.

Having taken a lodging within a moderate distance of my house, for the purpose of submitting to the operation for extirpation, which, from various causes, had been postponed, she had, by the 21st, become extremely large, and the skin of the lower part of the abdomen being œdematous, it was thought right to tap her again, lest the wound should fail to heal from this cause. I accordingly drew off four gallons and a quart of fluid, of the consistence of castor-oil, very mucilaginous to the touch, and containing a great proportion of albumen, as evinced by coagulation from heat. On the next and following day she was quite comfortable, with a moist skin, clean tongue, and healthy pulse, and no symptoms of inflammation arose afterwards.

Previous to the tapping, Dr. Blundell had seen the patient; and subsequently to it both he and myself renewed our examination of her state. The uterus appeared healthy. Some circumstances led Dr. B. to suspect adhesion of the sac to the parietes of the abdomen high on the left side; but where no obvious thickening of the adherent part has occurred, it is very difficult to ascertain with positive certainty the presence of such adhesions, and when I examined the abdomen carefully, on the day before that appointed for the operation, I could distinctly move the fundus of the tumor beneath my hand, when placed above it towards the scrobiculus cordis. Lateral motion was not clearly perceptible, nor is it when a certain amount of distension has been arrived at. Up to that period distinct rotundity is apt to be wanting in cases which, like this, rapidly proceed from flaccidity to tension by hastily-accumulating fluid.

Oct. 11th.—The preparations and arrangements were similar to those in my last two previous cases, and Dr. Blundell, Messrs. Bransby Cooper, Beale, Burrows, Law, and Dr. Wylie,

of St. Petersburg, attaché of his Imperial Highness the Grand Duke Michael of Russia, were present. The integuments, in the direction of the *linea alba*, a little below the points at which she had been tapped, were divided to the extent of an inch and a half; then the tendinous parts, and the peritoneum; in pinching up which the tension of the part impeded the action of the forceps more than on the former occasions. The peritoneum being entered, some adhesions were found between it and the sac, on each side of the wound, of small extent and chiefly filamentous: none in the direction of the pubes. They were very near the tapped part of the abdomen, and were therefore thought to be attributable to the operations of that kind she had undergone. On attempting to glide the surface of the tumor from side to side, little or no separate movement, as seen through the wound, could be produced. Nevertheless, I did not think it right to desist in uncertainty whether the adhesions were not so limited that they might be safely divided, or even divided at some risk, rather than abandon the patient to the sad fate of a woman labouring under ovarian dropsy of decidedly rapid progress. With this feeling, I prolonged the incision in the integuments, from a point a little to the left of the umbilicus to the first wound, and then divided from within, with the probe-pointed bistoury, the other structures upwards to the same extent; in all nearly five inches. I also divided adhesions on each side of the wound, hoping that they might prove of ascertainable limit; and this step affording me much additional means of investigating the state of matters. I made an examination with my finger on each side, but found, as I proceeded higher in the abdomen, the adhesions became wider in extent, stronger and more intimate. Dr. Blundell and Mr. Cooper were requested to convince themselves of this; and all present agreed that it was best to stay proceedings. I therefore carefully closed the wound with six stitches, laid a strip of lint along it, and over this applied supporting plaister and a broad flannel roller, just as if she had been tapped. It was observed that she had complained more than any of my former patients; doubtless the state of the parts divided

caused her to experience more pain than they did.

She was put to bed about five o'clock, complaining of some smarting pain at and near the wound. At nine that evening she still felt the same kind of pain, but in less degree, and had a pulse at 94: 80 being her ordinary pulse. The temperature of the room was 70. She had slept without an anodyne, and her skin was temperate and moist. No shivering nor chilliness had occurred, and she felt nearly as before the operation, except being much dejected at the circumstance of its not being completed.

Tea and toast-water, but nothing else to be taken.

12th.—Slept a good deal in the night, and feels better to-day, both in the wound and in herself. Has some soreness, but scarcely any pain: pulse under 90: skin perspiring gently: tongue moist: no general tenderness of the abdomen: passed her urine readily. Took only a pint of toast-water in the night. I visited her at 8 A.M., 1, and 11 P.M. At the last visit I found her pale and faintish, with a pulse at 100: tongue moist and clean: skin freely perspiring and temperate: free from pain, but a small part of the abdomen, near the wound, tender. The abstinence before and since the operation, and the warmth of the room, were evidently exhausting her, whilst the drain of the disease was not discontinued, as in my other cases, by removal of the secreting surface. Under such different circumstances I ordered her a glass of port wine, and then some toasted bread moistened with hot water and wine; and in the night she took some sago with wine.

Next day, 13th, her pulse was at 92. She had a clean tongue; a pretty good appetite; and as no fresh symptom had presented, mutton-broth, and tea and toast, were allowed; and at night, at her own desire, sago with wine again.

On the 14th her own report was, "nothing is the matter, only the place is a little sore." I tried the sides of the abdomen, and found no tenderness.

15th.—Dressed the wound, taking out the stitches: only about two drops of pus, near the umbilicus.

17th.—Again dressed the wound, and found that the distension of the abdomen, from her increasing size, had

caused it to gape for nearly two-thirds of its length, where I had hoped it was united; scarcely any pus. The gaping superficial; but sufficient to raise the question if tapping may not be necessary. The peritoneum, nevertheless, is shut by the parts laid down upon the cyst being adherent to it, and the deeper-seated textures of the line of wound united. Lint laid along the wound, and long supporting plaister carried over it, from side to side of the abdomen: the bandage firmly applied to the lower part of the abdomen, and complete freedom from pressure allowed above, by which the expansive power may there have vent, whilst the wound is preserved in contact, and its healing favoured.

18th.—Wound again dressed. The plan adopted appeared to be answering, and the tapping was accordingly deferred.

27th.—The wound having continued to heal steadily, was now almost perfectly cicatrized. She required to be tapped, and was anxious to return home. Four gallons and a quart of fluid were drawn off, and no unusual symptoms followed.

Nov. 2d.—The wound being soundly healed, and being herself as well as she usually has been after being tapped, she returned home. Twice since she has required tapping, viz. on the 27th of November, and the 26th of December. On each occasion upwards of four gallons of fluid, of the same character as before, were removed. Previously to the last of these operations, her distress from distension was much greater than heretofore; sleepless nights and general restlessness, retching and shortness of breath, rendering her life one continued scene of discomfort for several days. She is extremely anxious to be relieved, if possible, permanently; and is willing to incur the risk of almost any experimental measure. I have not thought it right to employ any.

A few practical remarks naturally arise out of the particulars just related; and they are of a satisfactory character in reference to the proceeding employed. The impunity of the measure affords a strong confirmation of the correctness of the principles on which these operations are based. As far as one case goes to shew it, the mere opening of the peritoneum, at a point rendered remote from the viscera by the

interposed bulk of disease, would seem to be a step attended by little risk, and may therefore be resorted to for information in obscure cases, as well as properly adopted to confirm the most assured diagnosis in those that are more clearly marked. When the disease has acquired great magnitude, a circumstance at present very common, the difficulty of ascertaining the presence or absence of adhesions to the peritoneum of the abdominal parietes is such, that mistakes are not unlikely to be made even by the most experienced. Various particulars of the history, &c. of cases assist in forming a probably correct opinion; but certainty seems hardly attainable without other than ordinary means. In the tentative incision we have a valuable auxiliary, and one which will, I think, always enable us to know if very broad and close attachments to the fore part of the peritoneum, where alone such occur, exist. Filamentous and band-like adhesions, elongated by the effect of motion, can be so easily dealt with in the major operation, that the ascertainment of their presence seems a secondary consideration. Somewhat close attachment to the moveable viscera may, however, exist without evidently restraining the mobility of the tumor. Nothing therefore supersedes the necessity of carefully studying the minutest anatomical circumstances, of a mechanical character, in each case; but the tentative incision, in addition to such study, will be found of great advantage. In making use of it, the eye and the finger are both serviceable. As soon as the incision is completed, the tumor, if not strongly and extensively attached to the parietes of the abdomen, may be made to glide from side to side, and to exhibit, at the opening, a free and ready mobility. The finger introduced ascertains, to a considerable extent, the freedom of the tumor from adhesions at a part where they are very likely to be found, especially when tapping has been previously resorted to; or discovers them, and informs the operator of their character.

Both this case and the succeeding one suggest the propriety of an earlier recourse to operation for the relief of such diseases. It is not my intention, just now, to enter upon the subject of the *causes* of adhesions; but whatever they may be, an opportunity for their

being brought into action is afforded by too great a postponement. The difficulties occasioned to operators, as well as the danger to the patient, are proportionately augmented: the former, perhaps, rendered insuperable; the latter, possibly, extreme.

REMARKS ON CONICAL CORNEA.

To the Editor of the Medical Gazette.

SIR,

My attention has just been directed to a letter in your journal of the 26th ult. from Mr. Middlemore, complaining that, in my paper on Conical Cornea, in the Dublin Journal of Medical Science, for January last, I have "overlooked his views on the nature and treatment of that singular malady, and attributed to others suggestions in reference to treatment which are due to him."

I have carefully endeavoured, throughout my paper (and I hoped I had succeeded), to award *suum cuique*. If I have failed in the attempt, my intentions must plead my apology.

Mr. Middlemore says, I have "omitted to state that he has considered conical cornea to be the result of a change effected in the cornea by the modifying and arranging powers of the absorbents."

I beg to assure Mr. Middlemore that I did not "overlook his views on the nature of the malady;" but, as I considered that they neither account for, nor explain the pathology of, conical cornea, I did not add, unnecessarily, to the very abundant proofs I adduced, that this was not understood.

I may perhaps be permitted so state that my theory of the disease is, that it "is analogous to hypertrophy, with dilatation, of the ventricles of the heart, and to aneurism" (p. 385); that it is "the product of growth" (p. 384); and is caused by impaired nervous energy of the membrane itself, the effect of which is, faulty action of the absorbent and nutrient vessels of the cornea. In other words, that "gastric or intestinal disturbance or irritation induces, through the medium of the par vagum, sympathetic, and ciliary nerves, faulty action of the absorbent and nutrient vessels of the cornea, the combined effect of which is conical cornea" (p. 385); that thinning of the cornea

internally would result from over activity of the former, whilst increased deposit externally would then, of necessity, take place from the latter (p. 384): that "this increased deposit would observe the same laws as do parts which are undergoing hypertrophy, where, though the matter effused assumes, at first, the form of nucleated cells, yet each tissue exerts a different assimilating influence on it, and causes the transformation of the cells into tissue of its own kind, and not into mere fibrous or cellular tissue, as is seen in inflammation" (note, p. 385).

In short, that the local disease has a constitutional origin, and that the treatment must be directed to the "diseased growth" through the same channel, the constitution.

Upon this my successful treatment of the disease affords the best comment.

It may not be altogether irrelevant to my subject to state, that I arrived at these conclusions by reasoning from effects to cause. Emetics, with purgatives, cure the disease. How do they effect this?

The nutrition of the eye is under the influence of the sympathetic. This influence is produced by virtue of its connexion with the lenticular ganglion—(p. 382). Gastric or intestinal disturbance or irritation would induce, through the par vagum, sympathetic, and fifth pair of nerves, a corresponding degree of disturbance in the functions of the absorbents and nutrient capillaries of the cornea—(p. 385).

Morbid anatomy has afforded evidence of the increased activity of both of these functions, in the central and internal thinning, and circumferential thickening—(pp. 359, 360, 384). Emetics, with purgatives, restore the healthy action of the par vagum and sympathetic, and these, as a consequence, exercise a healthy and controlling influence over the weakened absorbent and nutrient vessels of the cornea, the result of which is a slow, but progressive, retraction of the diseased corneal growth, and a consequent restoration of vision—(p. 387).

Mr. Middlemore ascribes the disease "to the modifying and arranging powers of the absorbents." Admitting, for the sake of argument, that the absorbents possess the powers attributed to them by Mr. Middlemore, I am yet at a loss to comprehend how any

amount of such powers can produce a *growth of parts*. Something more is wanting to account for its production. An American writer, Dr. Littell, goes even a step further than Mr. Middlemore, and suggests "that the disease probably depends upon some aberration in the assimilative and absorbent functions;" but this "aberration" in both functions will not explain the origin of the disease, for the aberration itself is only an effect; the cause is constitutional, the effect local.

I speak of causes and their effects; Mr. Middlemore of one only of two effects; Dr. Mackenzie of the other effect; and Dr. Littell of both effects; but none of them of the causes.

I submit, therefore, that "my views respecting the pathology of this singular disease are any thing but "an expansion" of Mr. Middlemore's, and that, therefore, on this point his observations fall to the ground.

On the other subject on which Mr. Middlemore considers it "necessary to assert his claims to priority of suggestion," I have nothing to offer beyond a statement of facts.

I found the operation detailed in Mr. Tyrrell's well-known work, published in 1840. Mr. Middlemore's name is not mentioned in connexion with it, neither is any allusion made to any "suggestions" from any other individual. Mr. Lawrence, in the second edition of his elaborate Treatise, published in 1841, refers (page 371) to Mr. Tyrrell's operation, but makes no allusion to Mr. Middlemore's Treatise, nor to his "suggestions."

The legitimate deduction to be drawn from the "scrupulously cautious and unobtrusive form" in which Mr. Middlemore gave these suggestions to the world, and from the impersonal mode of speech employed by him in his Treatise—"it has been proposed," "it is said"—was, that some other than Mr. Middlemore had *previously* "proposed," and "said." Hence, finding the operation and its results detailed in Mr. Tyrrell's work, and quoted by Mr. Lawrence, without any reference, in either case, to Mr. Middlemore, I gave Mr. Tyrrell the credit of the idea.

I am gratified, however, in having this opportunity of testifying to Mr. Middlemore's ingenuity in first proposing this operation, though, in my

opinion, I repeat, its advantages are of a very limited character—(pp. 372, 373).

In conclusion, I beg Mr. Middlemore will accept my best acknowledgments for his very complimentary and flattering remarks on my paper.—I am, sir,

Your obedient servant,

JAMES H. PICKFORD, M.D.

Brighton, Feb. 5, 1844.

PHTHISIS.

To the Editor of the Medical Gazette.

SIR,

SHOULD you think the following observations worthy of a place in your GAZETTE, they are at your service.

I am, sir,

Your obedient servant,

J. W. GRIFFITH, M.D. &c.

9, St. John's Square, Feb. 13, 1844.

In making the following observations, it is my intention merely to draw the attention of the profession to a circumstance which may possibly throw some light upon the explanation of a means adopted by nature for the purpose of temporarily arresting the progress of that fearful malady, phthisis, and the consideration of whether such means might not be imitated by medical treatment.

The reader is aware of the views of Liebig on the cause of death in chronic diseases; I will, however, quote his words. "In all chronic diseases death is produced by the same cause, viz. the chemical action of the atmosphere. When those substances are wanting whose function in the organism is to support the process of respiration; when the diseased organs are incapable of performing their proper function of producing these substances; when they have lost the power of transforming the food into that shape in which it may, by entering into combination with the oxygen of the air, protect the system from its influence; then the substance of the organs themselves, the fat of the body, the substance of the muscles, the nerves and the brain, are unavoidably consumed*."

In phthisis, I believe, we have a good example of this mode of death; for in

* Animal Chemistry, page 27.

this, although a disease of the lungs, death most frequently results from exhaustion. The nutrition of the body is impeded by the disease of the lymphatic and glandular system; the circulating mass is reduced by the excessive secretion, whether from the skin, bowels, lungs, or urinary organs; consequently so much of the vital fluid is consumed, that the heart's action ceases for want of its proper stimulant. In addition, then, to the means we possess of checking the diminution of the circulating mass from diarrhœa, sweats, &c., by opiates, metallic salts, &c., some means either of impeding the action of the oxygen of the air, or supplying a matter which may "burn" away, so as to protect the vital fluid and organs from combustion, is required. The first object is gained by nature when pregnancy occurs in the phthical female. It is well known that the progress of phthisis is temporarily arrested by pregnancy; but I am not aware that any probable explanation of such occurrence has been advanced. Such I consider to be found in the fact, that the fetal blood being entirely supplied with oxygen from that of the mother, a quantity of that oxygen is continually removed from the blood of the latter; the vital fluid is thus protected from its influence, and the fatal termination of the malady is postponed; and probably, if such a state, or one somewhat analogous, could be maintained, the progress of the case might be retarded, the cachectic or anæmic state of the body relieved, and the pulmonary disease remedied by counter-irritants, or what not.

A number of medicinal agents tend to fulfil a second indication—such as alcohol, camphor, pyro-acetic spirit, &c.: such agents, after being taken internally, speedily find their way into the blood, and are burnt off almost entirely by the lungs. It is rather curious to find here an explanation of the manner in which pyro-acetic spirit *might act** in relieving phthisis; and I

* That the action of it depends upon its power of dissolving tubercles is, I think, thoroughly unfounded; inasmuch as, for such end, it should be secreted in the liquid form by the pulmonary mucous membrane, which it doubtless is not: the greater part is probably "burned" off; but a portion probably passes as vapour; but tubercle is neither soluble in carbonic acid and water, the products of the combustion, nor in the vapour of pyro-acetic acid.

believe that such action, if such there be, depends entirely upon an operation of this kind; and one would imagine that other remedies should act in the same way, if given constantly, in small quantities and very frequently repeated, so as to keep the circulating mass impregnated with them.

Regarding the value of pyro-acetic spirit in phthisis, I have frequently used it, and have found its effects various. In some advanced cases I have found it of no use, not even alleviating the symptoms; but in two or three earlier cases I have seen it produce great relief to the symptoms, both stethoscopic and general. In one case in particular, a well-marked one of phthisis, the progress of the disease was entirely arrested, the cough almost entirely ceased, and the patient was discharged well: he remained so for about five months, when he was again attacked with pulmonary symptoms.

TUMOR OF THE ABDOMEN.

To the Editor of the Medical Gazette.

SIR,

IF the account of the accompanying case shall seem to you to possess sufficient interest, perhaps you will insert it in one of your forthcoming numbers.

I am, sir,

Your obedient servant,
ALEXANDER R. BROWN, M.D.
Cantab.

Stamford, Feb. 12, 1844.

Early in last May, I was requested to see, with Mr. Simpson, of this place, E. C. a girl, 14 years of age, of spare make, delicate appearance, fair complexion. At the time of my seeing her the countenance was indicative of severe suffering. Tongue moist, slightly coated far back. Bowels reported open with medicine. Stools loose, clay-coloured. Urine free, depositing a brick-dust sediment. Skin warm, and moist. Pulse about 80, soft. Catamenia not appeared.

She had been in ill health for two years, the greater part of which period she had been under medical treatment. Mr. Simpson had been attending her for about ten days. When he first saw her, she was suffering with intense pain in the abdomen occurring at irregular intervals, referred principally

to the left hypochondriac region, extending to the back, not aggravated by pressure. Temporary relief was afforded by full doses of opium.

On examining the abdomen, I discovered a tumor occupying the epigastrie and left hypochondriac regions, extending about three inches below the margin of the ribs. To my touch, it gave the idea of a firm, smooth, unyielding substance; its limits could, without difficulty, be traced, excepting its upper edge, which was covered by the ribs. Mr. Simpson thought, on firmer pressure, that it gave a crackling sensation to the fingers. Its situation somewhat reminded me of cases of enlarged spleen I have examined, instances of which, though not common, are by no means rare in this district. From the appearances of the stools, I was inclined to doubt whether it might not be connected with the liver: at the same time, I suggested the possibility of there being a collection of feces impacted in the colon. Full enemata of warm water, and subsequently of castor-oil and turpentine in thin gruel, had been ordered, the effect of which, though efficiently administered, tended to prove that there could be no obstruction in the lower bowel.

Having recently had some experience in the extraordinary retentive powers of that most admirably contrived, but ever getting wrong apparatus, the lower gut, I strongly urged that the same plan should be persevered in, together with a brisk purge of calomel or jalap. After a full enema of castor oil with turpentine had been twice repeated, she passed a substance about eight inches in length, and an inch and a half in diameter, composed of thread and worsted closely matted together: the substance was softened, and evidently disturbed from its original form, by the means which had been used to dislodge it. On questioning the girl, she confessed that for three years or more she had been in the habit of swallowing pieces of thread of different lengths: indeed, her taste appeared to have been as varied as the nature of the commodity she consumed would admit, for she drew largely on a worsted shawl which she occasionally wore.

From this time she ceased to have a recurrence of pain the ; stools became natural in colour, and her general health much improved. I had not an

opportunity of again examining the abdomen until ten days after she had passed the thread, when I found the tumor apparently not lessened in size, occupying the same situation as before. I then recommended that enemata of tepid water should be administered daily, and retained as long as possible, and that she should take an ounce and a half of olive oil every morning. This plan was persevered in for three weeks, but as the girl suffered no inconvenience from the presence of the "lump" in her body, both she and her friends were glad to discontinue it.

I lost sight of her until the second week in this year, when I had an opportunity of again examining her: the only difference I could observe was that the tumor had sank lower in the abdomen; it could be grasped between the finger and thumb, and readily moved from side to side: it is a flattened body about five inches in diameter.

The absence of bile in the stools before the thread was passed, is, perhaps, not the least interesting phenomenon in this case: jaundice might possibly in a short time have ensued, had not a portion of the substance been removed. Cases of jaundice, I believe, are far from uncommon, arising solely from obstructed thoroughfare in the colon: indeed, I call to mind a case which recently occurred in the practice of a friend of mine: mercury in its various forms, purgatives, &c. &c. proved useless: the man remained yellow: he was ultimately relieved by a steady perseverance in full enemata of warm water.

MEDICAL GAZETTE.

Artis Medice tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

MEDICAL BENEFIT SOCIETIES.

IN our number of last week we called attention to the dinner of the Society for Relief of Widows and Orphans of Medical men in London and its Vicinity, then about to take place, and we quoted from the preface to the laws some facts

respecting the origin, progress, and working of the Society. It is quite impossible to doubt that an institution which in little more than fifty years has accumulated forty-one thousand pounds, and distributed thirty-two thousand, must have worked powerfully for good or for evil on that profession, and in that locality to which its operations are confined. The general impression arising from the facts quoted is highly in favour of this institution, and is doubtless substantially correct, but it cannot be concealed, and should not be denied, that this society is liable to certain objections common to all those institutions which have for their object the systematic relief of poverty. Whatever these objections are, and however ungracious it may be to raise doubts which may stay the hand of the benevolent, or weaken the resolutions of the provident, it is better to examine them calmly, than to deny their validity or to decry their propriety. The whole of the argument against this systematic provision is directed in support of these two assertions—viz. 1st, that it taxes the most diligent, careful, and efficient members of society, for the benefit of the idle, the improvident, and the worthless; 2dly, that it removes the principal stimulus to industry, economy, and prudence,—virtues which improve personal character, make success more general, and failure more feared and less frequent.

Much, very much, may be urged on this side. Whether it be doled out at a convent gate, to a crowd, who, warmed and cheered by the sun of Italy, require but the absence of starvation to secure enjoyment; or at a workhouse during an English winter; a subsistence that may be had for asking, is always fatal to industry and prudence. The more easily alms may be obtained, and the larger their amount, the larger will be the propor-

tion of those who calculate on receiving them, and the greater deterioration in the quality of its members will society suffer in consequence.

The old poor law, it was said, held out a premium to dependence on parish relief under the contingencies of old age, widowhood, sickness, and want of employment. The three first were bad enough, but the last was intolerable, and it was doubtless the abuses of a parish provision against want of work, and the embarrassments those abuses created in the always complicated question of wages, which raised up a party at once powerful enough, active enough, and discontented enough, to heave up the burden and alter its form and pressure. How easily the country lies now, or how long it will lie, under the new poor law, is another affair. Already slop-work, or the making of clothes by paupers, shews, by the police reports, that part of the pressure has been shifted to a class of manufacturers, who, living only just above starvation point, cannot stand the reduction produced by competing with paupers.

But, some how or other, the verb *to give*, with all its inflections, derivatives, and compounds, has found a place among the parts of speech in every known language. Put the screw on as we will, apply the test of destitution till the flesh creeps at the products of the experiment, button up the breeches pocket never so tightly, there is a something which tells us that man is not only a paying animal, but a giving animal; and that although this natural appetite or propensity must not be indulged weakly and to excess, yet neither can it safely be altogether repressed. It must be subjected, then, like other natural appetites, to the control of reason and conscience. Those who do not give systematically are apt to give injudiciously, and this even when the total amount of their

givings is incredibly small. We are apt to confine the idea of indiscriminate benevolence to those persons whose name is seen to every subscription list, but a man who only once in a year gives a penny in the street, may yet bestow that penny most injudiciously, and do all the social damage of which the amount is capable.

Let us see if there be any thing in a systematic provision for the poor of our own calling, which may be placed before us in the light of a practical question, to which every man is bound to give his best attention, and, after weighing the evidence, and considering the probabilities where direct evidence cannot be produced, to make up his mind decidedly, and to act consistently.

We believe that a diligent and accurate search would establish the fact, that all trades, crafts, or other forms of skill and industry whatever, which obtained powers of exclusion and restriction, whether as to the numbers admitted, the qualification of its members, the privilege of practising in a particular locality, or any form or amount of corporate privilege whatsoever, did also recognize the duty or the propriety of making provision for the aged or destitute among those once admitted within their boundaries. The recognition of this principle will be found more or less complete in different cases, greatly varying in the form or the degree, the time or the mode, in which it has been acted upon; sometimes, with forethought and intention, interwoven into the original plan and constitution of a body; sometimes arising out of unforeseen contingencies; sometimes made necessary by partial distress within the body corporate; sometimes forcibly imposed by a superior power or pressure from without. The member of a corporate body became, by birth, adoption, service, purchase, or otherwise, member

of a large and powerful family. These family compacts or associations were but partial substitutes for those still older family compacts, the feudal dependencies, which bound lord and vassal together for mutual support and protection. The early Christian church—the primitive brotherhood—is the earliest great family compact to which we need trace all these, though the strong analogies of Jewish polity and patriarchal life cannot be wholly overlooked. The forms of feudalism long outlived the substance. Followers and nominal dependents of men of quality, when at length turned adrift, became the “masterless men” who infested England under Elizabeth. Bardolph, Pistol, and Nym, are capital specimens of this class; their characters, and the development of their history, though the scene is laid during the battle of Agincourt, were no doubt drawn from the life, and abundantly explain why the whipping of “vagabonds and masterless men” after the second conviction, and hanging after the third, seemed a wholesome measure of state policy, and, coupled with the compulsory provision for the aged sick and needy, by the 43d of Elizabeth, in lieu of the religious establishments lately abolished, not an over harsh cure for a dangerous nuisance.

Corporate bodies have, of late years, received some severe shocks. Their privileges of exclusion, as well as those of internal police and government, have been materially diminished, partly by the pressure of opinion from without, partly by apathy within. In many trades the tests of competence hardly exist, or are hardly ever applied, each man is free to follow any calling he thinks fit, when, where, and how he pleases, with small and partial exceptions for particular trades and certain localities. Even in those callings, where public safety most requires

proof of education and competence, such as our own of medicine, how little coercive power is practically retained by the corporate bodies. They confer, indeed, the stamp of legality and sufficiency upon voluntary candidates; but they have, one by one, almost wholly relinquished the privileges of extrusion for misconduct, and of punishment for practising without their license. The tests of competence, indeed, they have each gradually raised; but the tide of education has risen too, and soon overpassing the barriers successively opposed to it, has inundated each department of our art with a deluge of the qualified and the unemployed. The Apothecaries' Company, indeed, is not water-tight; for the druggists, who could not rise above their barriers, have leaked in from below, and now threaten to swamp them.

Masterless men, then, there are in our profession, sick, and aged and poor there are too, and the widow and orphan, of course. Are we to do nothing for any such? Take the last class only. Shall we wait till the widow of our neighbour forces her way into our houses, wrings alms from us by a tale of misery and want, and leaves us a degraded mendicant? Surely not. Shall we establish a fund by a contribution from each on entering the profession, which shall either be claimed by all as an insurance, or reserved for division among the destitute? The insurance, to be effectual, would be expensive; the other plan might be well, but would be open to all the objections of a compulsory tax on the industrious and prudent,—who are generally, also, the successful,—for the benefit of the idle and improvident, who generally fail. A third and middle way occurs, viz. to *help those who help themselves*, by contributing to a voluntary fund, which is divided among the needy families of deceased members. In this way none can be benefited but the

needy, and none encouraged but the provident. The rich will not receive what they do not want, and the poor need not blush to receive what they do. Such a fund the Society we have quoted possesses.

It is said by some that a society of this kind tempts to too early marriage, and the neglect of insurance; that a man, who ought to make competent provision for his family at his death, is apt to content himself with a miserable pittance only just above pauperism. This cannot be wholly denied, nor early and improvident marriages defended: but would not such a man leave his family *in* pauperism, instead of *above* it? and is not society the gainer by his increase of prudence, slight as it is? But besides, many men, at the time of beginning practice, cannot afford to effect an adequate insurance! To such men a small insurance against absolute want is no bad beginning till their means are greater. We know that a most eminent surgeon, whose opinion deserves the very highest respect, entertains this objection. We know, also, however, that he is an enrolled member, and a liberal contributor to its funds. Of such objectors the more the better*.

If this Society had the support of every qualified member of the profession within the limits it embraces—if the funds were administered with the prudence and justice that seem to have marked its course—if the test of the ballot in the admission of members were applied with kindness, yet with due care to *maintain professional character*, the profession would gain incalculably—we might almost say, would

* The example of this gentleman is the more valuable, too, as it proves that though he thinks this mode of doing good not the best that might be devised, he believes it to be the best that exists. His practical benevolence, too, is not likely to be tinged with the enthusiasm of more zealous partizans, which, though useful in rousing the indolent and the apathetic, is suspicious to the cautious and prudent.

be secure from some of the most serious evils and anxieties that now beset the conscientious discharge of their laborious duties.

WIDOWS AND ORPHANS OF MEDICAL MEN.

THE annual dinner of the Society for Relief of the Widows and Orphans of Medical Men in London and its vicinity, took place on Tuesday last, at the Freemasons' Tavern, and was rather less numerously attended than usual. His R.H. the Duke of Cambridge, the Patron, declined to preside this year, and the President, Sir Henry Hallford, was prevented by illness. The chair was therefore taken by Sir Charles Mansfield Clarke, Bart., senior Vice-President.

The object of this institution is to afford relief to those widows and young children of deceased members who may be left in distressed circumstances. It was founded in 1788, by a few eminent physicians, viz. Dr. Denman, father of the present Lord Denman, Dr. Dennison, Dr. Douglas, Dr. Sims, and Dr. Squire; assisted by Mr. Randall, and by Mr. Chamberlain as Secretary. Though consisting of less than 350 members, yet, by judicious adherence to wise principles, it has afforded, since 1793, permanent yearly relief to 77 widows and 124 children, and accumulated a capital of £41,000. 31 widows and 24 children were relieved last year; the sum granted to a widow being from £30 to £35, with a few pounds for each child. The chairman expressed his regret that the grants were so small, but that could not be helped while the number of members was so limited, and the support of the wealthy, both in and out of the profession, so shamefully withheld or so sparingly given: more good could not be done without more means: but he congratulated the Society on being united together to secure even such a pittance to the families of the honest, scientific, and qualified regular practitioner, especially at a time when those, who really ought to know better, support and encourage the most fraudulent quackery. He had no doubt, however, that the public would, in time, find out their mistake, and recognise the medical practitioner as the best friend and adviser in the long

run. The Rev. Samuel Wix, Vicar of St. Bartholomew's Hospital; Mr. Tudor, of the Stock Exchange; and several medical visitors, were present. Donations were received from the Ladies Elizabeth and Louisa Cornwallis, Mrs. Thwaites, Rev. S. Wix, Dr. Outram, Mr. Phipps, and Mr. Tudor; also from Messrs. Blagden, Chilver, Pennington, Probert, Stone, Squibb, Walne, Ware, and other members present.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

Tuesday, February 13, 1844.

BRANSBY B. COOPER, ESQ. F.R.S., VICE-PRESIDENT, IN THE CHAIR.

Case of extensive Carcinoma of the Lungs; with some Practical Remarks. By GEO. BURROWS, M.D., Physician to St. Bartholomew's Hospital.

THE author adverts to two conditions in which carcinoma is found in the lungs, either as a primary or secondary affection. In the latter it gives rise to few pulmonary symptoms, and produces but little change in the pulmonary tissues. Primary cancer of the lungs, on the other hand, is a most serious disease. Very large portions of a lung become infiltrated with the morbid deposit; and this is often combined with mediastinal tumors of a similar character. The symptoms which attend on these formations are most distressing and perplexing: they partly arise from the gradual consolidation of the lung, and partly from pressure on the respiratory tubes and blood-vessels at the root of the lung.

CASE.—A married woman, aged 20, was admitted into St. Bartholomew's Hospital, on 22d April, 1843, giving the following history of her complaints. She had been healthy until six months ago, when she was attacked with pain beneath the sternum, cough, and expectoration. She was delivered of her first child about three months since, after which dyspnoea and cough increased, with some swelling of the cervical glands. From this period her health declined, and a month before admission she was attacked with hæmoptysis. On admission, her face was pallid and bloated, with rather livid lips; respirations 40, with much dilatation of the nostrils; pulse 132, small; decubitus on the back, inclining to the right side. She complained of pain beneath the sternum; distressing paroxysms of cough, leaving her breathless and panting; expectoration scanty; the sputa bloody, resembling red currant juice; the cervical glands on the right side swollen, hard, and tender,

with enlarged veins passing over them; the external jugular vein much distended.

Upon auscultation and percussion the left lung appeared to be healthy. On the right side there was a feeble respiratory murmur in the upper third; in the lower two-thirds there was a varying amount of bronchial breathing; the expiration prolonged, accompanied with a modification of sibilus resembling a chirp. On percussion the sound was extremely dull all over the lower two-thirds of the right lung. The voice was so weak and husky, that no vocal phenomena could be discovered. The heart's sounds were natural, and not transmitted beyond the cardiac region.

The physical signs in some respects indicated consolidation of the larger part of the right lung, while in others they were those of pleuritic effusion. This latter supposition was supported by the measurement of the chest, which gave an excess of an inch and a half to the right over the left side, as well as the constant posture of the patient on her right side.

The author ventured to form the diagnosis of malignant disease of the right lung, partly founding that opinion on the physical signs, which did not correspond with any of the ordinary forms of thoracic disease, and partly on the history of the complaint. A few days after this examination, the cervical glands increased much in size, occasioning additional suffering by pressure on the trachea: the face, throat, right arm and mamma, became very anasarctous: the dyspnoea, cough, and peculiar bloody expectoration, continued: the posture was almost entirely on the right side, and the physical signs of pleuritic effusions more decided.

It now became a question whether paracentesis thoracis ought not to be performed to relieve her suffocative dyspnoea: the operation was not considered right, as the author still adhered to the opinion of extensive malignant formations in the right lung. Without further change in the symptoms, the woman expired at the end of a fortnight. The body was examined nine hours after death.

The heart and left lung were found healthy; the right pleura contained Oiv. of olive-brown coloured serum; the lung had not collapsed, but stood out projecting into the pleural cavity. The upper lobe was not much altered; the middle and lower lobes felt quite solid, a white lobulated tumor, something like a mass of suet, projected from the lower lobe. Towards the root of the lung was another dull white tumor, which had thrust the lung up from the spinal column. The substance of the middle lobe appeared to be continuous with these tumors. The pleura covering the lower lobe was dark coloured, with numerous enlarged

blood-vessels ramifying on the surface. Upon making sections of the middle lobe and tumors, their substance was of a uniform dull white colour and rather soft; in some parts there were a few minute vessels; the surfaces yielded, on compression, a white creamy fluid in considerable quantity. The superficial parts of the lower lobe were converted into a dark brownish friable substance, studded with streaks and patches of white matter. Portions of the carcinomatous substance had also made their way into the right bronchus and right pulmonary vein.

In the upper part of the anterior mediastinum there was another carcinomatous tumor; and upon making sections of the enlarged cervical glands, they presented similar changes. All the abdominal and pelvic viscera were examined, and found free from carcinoma.

The author then proceeds to give an account of our knowledge of carcinoma in the lungs, referring to the works of Laennec, Andral, Stokes, Sims, and Walsh; and points out the rapidity with which the diagnosis of this disease has improved. The paper is concluded by the following statement:—"That when a patient has long been suffering from severe affection of the respiratory organs, with physical signs offering close analogies to those of consolidation of the lung, or of copious pleuritic effusion, and yet presenting anomalies not compatible with either of those morbid conditions; and when the history of the case does not accord with that of tubercular infiltration of the lung, nor of chronic pneumonia, nor pleurisy, malignant disease should be suspected. In addition, if the countenance become bloated, the eyeballs prominent, the throat swollen, with œdema of the arm on the affected side; enlargement of the superficial, cervical, and thoracic veins; dysphagia, with enlarged glands or other tumors on the surface of the body; and the cough be accompanied with currant-juice sputa, the diagnosis of malignant disease in the lung may be considered complete."

—

On the Effect of Water-Drinking in the cure of Gout. By JOHN BOSTOCK, M.D. F.R.S.

We have lately heard so much, not only of the moral, but of the physical effects of water-drinking, as practised either on the more moderate scale of the disciples of Father Mathew, or in the more profuse ingurgitations of the hydropathists, that I have conceived it may not be altogether uninteresting to the Medico-Chirurgical Society to hear the account of a few observations which I have had an opportunity of making upon the effect of these two processes. The first case to which I propose to direct the attention of

the Society is that of a gentleman, 70 years of age, who had been, from an early period of his life, subject to very frequent attacks of gout, the predisposition to which complaint is inherited from his parents. Connected with this, he has been a constant sufferer from stomach affections of various kinds; acidity, flatulence, heart-burn, irregularity of the bowels, and, in short, from every one of the affections which are enumerated in Cullen's well-known definition of dyspepsia. His mode of life was regular, and moderately active, and his diet what might be styled temperate, although not abstemious. He had, indeed, been advised by his medical friends to take wine in moderate quantity; he had occasionally employed ale, porter, and brandy and water, but never in what could be considered an excessive quantity. In this way he had passed about 40 years, seldom actually confined by indisposition, but almost always subject to a succession of ailments, which rendered it necessary to have recourse to medicines of various kinds, and, more especially, to alkalies, which were taken in large quantity, and, as the symptoms appeared to indicate, to purgatives or to sedatives, and to a variety of tonics and stimulants. During this period the renal secretion was seldom in what could be considered as a perfectly healthy state; it was sometimes loaded with deposits, and of high specific gravity; sometimes of low specific gravity, limpid, and aqueous; sometimes very copious, at other times scanty; while its chemical constitution was most variable both as to the nature and the proportion of its saline contents.

About four years ago, in consequence of the accession of certain alarming symptoms, of a new description, which were supposed to require the antiphlogistic treatment, the patient was ordered by his medical attendants to reduce his system of diet, and, more especially, to abstain entirely from fermented liquors, or distilled spirits of any description. By this restriction, and by other appropriate remedies, the threatened disease was averted. And besides this fortunate result, the patient found his general state of health and feelings so much improved by the change of diet, that the abstinence from all kinds of liquors has been strictly adhered to up to the present period. The effect has been, that he has lost all the dyspeptic symptoms, to which he had been subject for upwards of forty years, and, what I am more particularly desirous of pointing out to the Society, the renal secretion has been now, for a long period, in a perfectly natural state: it is nearly uniform in its specific gravity, and is totally free from all the morbid deposits which were before seldom absent from it. And there is a circumstance connected with

it, which I conceive to be particularly deserving of attention, that although of an average specific gravity, and containing the proper proportion of urea and saline ingredients, it is uniformly increased in quantity, so that there has been now, for several months, considerably more of these substances discharged from the system than was formerly the case. It would appear, therefore, that the abstraction of the alcohol has produced a more healthy state of the digestive and secreting organs, so that the functions of the kidney are more actively and effectively performed. As a counterbalance to this improved state of the constitution, the only inconvenience experienced by the patient is the frequent and urgent calls to empty the bladder; these occur during the day at short intervals, and the night is seldom passed without at least two evacuations. To prevent this inconvenience, he has, for some time, diminished considerably the quantity of water, as well as of liquids of all kinds employed in diet; but it does not, at present, appear that this diminution has had much effect upon the amount or the quantity of the fluid discharged.

At the same time that I was making these observations upon the effect of what has been technically styled the Temperance system, an opportunity occurred to me of learning the result of a complete process of hydropathy. A gentleman, of nearly the same age with the former, who, like him, inherited a gouty diathesis, and had, for many years, suffered severely from the complaint, was induced to try the effects of the new practice, and according to the account which I received from himself, underwent the whole discipline in the most complete style. The quantity of fluid which was swallowed, could I have doubted the veracity of my informant, I should have conceived it impossible to have been received into the stomach, and to this were added the rubbings, sweatings, and the other adjuncts; among which, it must be observed, were a regulated diet, bodily exercise, fresh air, and the absence of many of those causes of disease which are the necessary attendants upon the life of a man who is either devoted to business, or who moves in the higher circles of society. The result, however, was, that the patient returned from his campaign, having subdued his old enemy, the gout, and in a better state of health than he had experienced for many years. He still continues to imbibe water in large quantity, and it is not therefore surprising that a large quantity of fluid should be voided. Indeed, while undergoing the complete process of hydropathization, the animal body may be regarded as a simple conduit, much resembling the well known little figure that adorns the corner of one of the streets in Brussels.

It appeared to me, as far as I was able to form an opinion, that, in this case, as in the former, the specific formation of the kidney was considerably increased; but I had not the means of ascertaining the fact by an absolute experiment, as in the other instance.

Viewing the result of these two cases, and more especially comparing them with each other, we are induced to inquire, what practical inferences can be deduced from them. Now, taking into account all the circumstances, I conceive there can be no doubt that a decided benefit was obtained in each case, that a disease was removed of many years' standing, and which had resisted various means that had been previously employed. We may then inquire, to what particular circumstances are the beneficial results to be more immediately referred; to the abstraction of alcohol, to the imbibition of water, or to any other remedial agents. In the first case the abstraction of alcohol would appear to be the only circumstance that can be conceived to have produced the effect. The water taken was in moderate quantity, and although other means were employed, which might have a tendency to improve the general health, they were not such as can be conceived sufficiently powerful to produce so great a change in the state of the constitution. In the second case I should conceive, that although much of the benefit obtained may be ascribed to the abstraction of the alcohol, yet we can scarcely imagine that the prodigious influx of water into the stomach can have been without its influence on the system. Mechanical and unscientific as the idea may appear, I confess I am disposed to attribute a considerable effect to the complete removal of all the offensive matter which had polluted the vessels, thus thoroughly rinsing them out, and leaving them in a clear state to receive a supply of more healthy fluids. Nor are we to regard the adjuncts as, some of them at least, without their influence: although I must think that many of them were carried to an empirical, and I will say, a ludicrous extent. The annals of medicine from the earliest periods contain accounts of the temples of health, which were under the direction of the Aesclepiadæ; the sacred fountains of Greece and Italy, to which Hippocrates and Celsus sent their patients; the miraculous springs, dedicated to various Saints, male and female, in the middle ages; and the acknowledged cures performed in modern times by waters, of which the chief peculiarity consists in their purity; all which may be placed in the same category, and which may serve to explain a part at least of the benefit derived from hydropathy.

The anniversary meeting will be held on Friday, the 1st of March, at 3 o'clock P.M.

CHANGES IN THE CLIMATE OF FRANCE.

From a paper read by M. Fuster, at the Academy of Sciences.

In the time of Julius Cæsar, the climate of Gaul was very harsh; the winter was very cold, came on early, and lasted long; for it began in October, and continued till April. Every navigable river, the Rhone included, was frozen over; and the ice was so strong as to bear armies and their baggage in safety.

Gaul was then inundated with rain; and the storms were so violent that they reached the natives even amid the thick covering of their forests. Neither the vine nor the fig could be cultivated, and the country was overspread with immense forests, covering, according to M. Fuster, forty-six millions of hectares of land.

The climate rapidly improved, as is shown by the ascending progress of the cultivation of the vine in the first century.

Before Strabo, it stopped at the foot of the Cevennes; it then began to pass this barrier. Columella, at a later period, met with it among the Allobroges (Dauphiny); and Pliny saw the vine growing spontaneously in the Vivarais, propagating itself in the district of Vienne, then reach Auvergne, and get as far as the Sequani or Franche-Comté. Indeed, in the 69th year of our era, when Domitian ordered the vines to be rooted up, they had been cultivated beyond the environs of Autun and the territory of the Bituriges (Berry.) The climate of France continued to improve; and when the Emperor Probus allowed the Gauls to plant the vine again, its culture, which had before stopped at the 47th degree of latitude, now extended to the north, along the banks of the Seine. The fig-tree, more sensitive to cold, which at the commencement of the Christian era had stopped on this side of the Cevennes, rapidly followed the vine in its progress. Julian, who in the middle of the fourth century was in the little town of Lutetia, gives a charming picture of the district. He extols the extreme mildness of its temperature, the excellence of its vines, and the rapid multiplication of its fig trees. He also tells us in one of his letters, that in the north of Gaul the corn was ripe at the summer solstice.

That the south had improved as well as the north, Ausonius of Bordeaux, and Silius Apollinaris, do not permit us to doubt. The forests were diminishing as agriculture and civilization made progress.

In the fifth century, when the Franks became masters of Gaul, its climate was even milder than in the time of Julian; it was cha-

acterized by rain, followed by inundations, and intense heat, early and prolonged. Hence there were two flowering and two fruit seasons almost every year: and the vine reached the most northern points of the kingdom. It covered Normandy, Brittany, and Picardy; all these vines afforded fine crops, and many furnished very good wine. The vintage generally occurred in September, and sometimes even in August. In these northern provinces the harvest was reaped in the latter half of July, as appears from charters, contracts of sale, &c.

The ninth century marks the limits of the progress of the climate of France. It lost nothing, however, before the twelfth century, and seemed to remain stationary for two hundred years. Its winters were still made up of rain and tempest; the vine still covered the whole of the north. The harvest was still reaped in the north at the end of July, and the vintage was at the end of September.

The north-east of France afforded vines and vintages as late as the thirteenth century. After this period a change gradually took place for the worse. At last, in the seventeenth and eighteenth centuries, Picardy lost the remainder of its vineyards, as well as Normandy and Brittany. The wines of the environs of Paris fell into discredit; in the south, the orange, the lemon, and the citron tree, could no longer stand the climate of Languedoc in the open ground; the sugar cane in Provence now required the shelter of the greenhouse; lastly, the olive, which had been ascending, retrograded towards the sea.

In the seventeenth century Provence produced palm trees, of which the fruit, according to the report of Davity the cosmographer, was equal to the dates of Africa; and he adds, that the whole plain of this district, between Orgon, Aix, and Marseilles, by St. Chamaz, Miramas, Senas, and Malmort, was rich in orange, lemon, and palm trees, as well as the country between Marseilles, Hyeres, Frejus, &c. At the same period, Perpignan, in Roussillon, possessed two long rows of centenary orange trees, planted in the open air in a broad street.

The eighteenth century deprived our climate of all these advantages. It witnessed the last vintages of Normandy and Brittany; it impoverished the vineyards of Maine, and reduced the vines of Anjou, Orleans, and Sens, to mediocrity; it drove the olive tree below Carcassonne, and limited its cultivation on the eastern side; it deprived the palms of Provence of their fruit, drove the orange trees of Roussillon into greenhouses or sheltered places, and confined those of Provence beyond Toulouse, to the territory of Hyeres, Vence, Connote, and Nice.

When Arthur Young made his celebrated

tour in France in 1787 and 1789, he mentioned a characteristic feature of the districts where the vine no longer prospered, namely, the great quantity of fruit which they bore, particularly plums, peaches, cherries, grapes, and melons; and he makes the limits for the cultivation of the olive extend from Carcassonne to Montelimart. All this is no longer the case. Grapes no longer ripen without difficulty in the open air in Brittany, Normandy, and Picardy; fruit-trees (especially those bearing stone-fruit), which in his time were so productive in those provinces, now succeed only as espaliers. The olive tree has shrunk back on every side; it does not grow at Carcassonne; its recession in Provence is a fact generally acknowledged; it is no longer cultivated on the left bank of the Rhone, beyond Douzere, four or five leagues to the south of Montelimart. M. A. de Candolle, in 1835, fixed the extent of its retrogression since 1789, in the department of the Aude, at five myriamètres (about 25 miles.) Moreover, according to Malte-Brun, wheat affords nearly a quarter less nutritious matter now than in 1788.—Abridged from the *Gazette Medicale*, Jan. 20, 1844.

MURIATE OF AMMONIA INTERNALLY.

IN the medical treatment of pleurisy, and subacute inflammation of the lungs, and congestions of the mucous membrane, I have availed myself very satisfactorily of a German remedy, which is almost universally employed in such cases, viz. the muriate of ammonia.

In English practice it has generally been confined to external use, whereas it is employed by the Germans in a great variety of internal complaints. It usurps the place of the nitrate of potash in British practice. Its employment is confined to sub-acute affections, congestive states of the mucous membrane of the bronchia, and chronic affections of the serous membrane: where the inflammation runs very high, the nitrate of potash and soda are preferred. It has no very decided action on the system, although it sometimes stimulates the kidneys; but it is considered to be deobstruent, and to unload the vessels gradually, so that convalescence is achieved without any critical evacuation. It relieves thirst, and the tongue gets unloaded under its use. It has certainly a decided action on the mucous membrane generally, and is useful in old coughs accompanied by gastric derangement.

I was loath to employ it when I first commenced practice in St. Petersburg, but the good recommendation of my German

colleagues overcame my scruples, and during the last ten years of my sojourn among them, I prescribed it most freely, and have reason to speak most highly of it. I never failed to use it in the many cases which that climate affords of such affections as are benefited by it.

Its combination with the tartrate of antimony, in a solution of extract of liquorice, is a valuable prescription. The following is the form usually employed:—

R Ammoniac Mur. ʒj.; Ext. Glycyrrhiz. ʒiij.; Antim. Tartar. gr. ij.; Aquæ destil. ʒviij. M.

A large table-spoonful of this mixture is administered every two hours. The antimony forms no inconsiderable part in the operation. When its nauseating effects have made sufficient impression upon the disease, it may be withdrawn, and the muriate continued by itself. In many cases the latter is only administered.

Stomach coughs are greatly benefited by it. Where the tongue is loaded, it cleans rapidly under its use. A variety of affections of the mucous membrane, sore throats, enlarged tonsils, relaxation of the uvula, &c. feel its influence.—*Sir G. Leferre on Thermal Comfort.*

ON THE STATE OF THE HEART IN THE OLD.

Collected from Cases at the Salpêtrière,

By M. NEUCOURT.

IF there is a great variety of opinions on the state and size of the heart in the adult, it is the same with that of the old; and the numerous measurements of MM. Bizot, Bouillaud, and Clendinning, are far from having ascertained anything certain as to the normal size of the heart, even in the adult. No inquiry of the kind had been made concerning the heart of the aged before M. Neucourt's researches; but he does not attempt to conceal that they are insufficient, from the small number of cases which he has examined, and—we would add—from the immense variety of the productions of nature, which makes it difficult to fix her limits. M. Neucourt's cases were all women, and at least 60 years of age. We will not copy all the figures which the author has given, representing his varied measurements of the heart; but we will confine ourselves to quoting the thickness of the parietes of the left ventricle in hearts which were not hypertrophied. It was as follows:—

Maximum . . .	26 millimetres.
Mean . . .	16 „
Minimum . . .	8 „

“These figures,” says the author, with great propriety, “show how distant are the numbers between which the normal thickness of this ventricle varies in the aged, and how vague are the assertions of authors, who often say that the heart is hypertrophied, or that its parietes are attenuated, without entering into particulars. In limiting ourselves to these figures, we only give the greatest thickness of the wall of the left ventricle, and we are thus far from having an exact notion of it. In fact, it grows thinner and thinner, from the base to the apex, where it is sometimes not more than two or three millimetres thick, or even disappears completely, and is replaced by fatty tissues, so that a few columnæ carneæ interlaced with fat are the only obturators of the heart at this point. The possibility of such a state ought to be taken into consideration, and seems calculated to overturn some physiological theories concerning the action of the heart.”

The following are the practical conclusions which may be collected from the author's paper:—

1. The heart in the aged is at least as large as in the adult, and, if there is a difference, it is on the side of the former.

2. The thickness of the parietes is rather greater in old age than at any other time of life.

3. All the orifices are rather larger than in the adult.

4. Ossifications of the aorta do not of themselves necessarily produce derangement in the functions of the heart.

5. No sign shows their presence, when they are unaccompanied either by contraction or by insufficiency of the orifices where they occur.

6. Ossifications of the abdominal aorta are more frequent than in any other part of the artery.

7. It is almost certain that diseases of the heart, whether contraction or weakness (*insuffisance*), are discoverable in the old by the same auscultatory signs as in the adult.

8. After death, the cavities of the heart contract the more closely, in proportion to the rapidity with which death took place.

9. There may be irregular sounds at the orifices of the heart without disturbance of its functions.

10. Diseases of the heart, with very serious impairment of its functions, may exist for a great number of years without causing death.—*Gazette Medicale*, abridged from the *Archives Générales*.

PROBABLE DURATION OF LIFE.

THE probable duration of life—the *Vie probable* of the French—is seen at once

by inspecting the table; it is the time in which the number born is reduced one-half; in the English table, $45\frac{1}{2}$ years. It is probable, or, in Halley's words, "an even wager," that a child will live $45\frac{1}{2}$ years; for the 100,000 are reduced to 50,301—nearly half their number—by the age 45; there is therefore nearly an equal number of chances (50,000) in favour of living to and of dying before the age $45\frac{1}{2}$. The *probable* life of a boy is 44, of a girl 47 years. How long is it probable that a woman aged 25 will live? The "living" against 25 in the table is 31,337, the half of which is 15,668, a number attained at the age 66; 41 years therefore is the *probable* duration of her life. What is the "probable life" of a man at the age of 60? The number against the age is 18,808; and the half of 18,808 is 9,404, to which the 18,801 are reduced at the age 73; at 60 therefore it is *probable* that a man will live 13 years.

Suppose that it were desired to ascertain the influence of factory labour, or any other employment—of residence in a school or city; the first point to be determined would be the average probability of life according to the English Life table; say that the children enter at 10 years of age, then as in the Table, 70,612 is against the age and 68,627 against the age 15, the average probability of living five years is $\frac{70612+68627}{2}$, and the degree in which this probability is diminished or increased measures exactly the influence of the circumstances in which the children are placed.

Upon adding up the column of "living" the sum of the numbers will be found to amount to 4,165,890; subtract half 100,000 from this, and 4,115,890, the number of the years which the 100,000 persons live, will be obtained. Divide the years of life, 4,115,890, by 100,000, and the quotient, 41.16, will be the mean age. This is called the *Expectation of Life*—*Vie Moyenne* of Deparcieux; for males it is 40 years, females 42 years, and for both sexes 41 years. By repeating the process the expectation of life at each year of age is obtained; at five years it is 50 years; at ten 47; at twenty 40; at thirty 34; at forty 27; at fifty 21; at sixty 14, &c. &c. The average age at which persons aged 30 will die is 64 years, and 74 is the average age at which sexagenarians will die. — *From the Registrar-General's Report.*

STRYCHNINE IN INFLUENZA.

THE prevailing epidemic influenza made its first appearance during the present season, in Gettysburg, Pa., about the 1st of July. The disease was characterised by the usual symptoms. About two-thirds of the whole number of inhabitants became subjects of the disease, not one half of whom, however,

deemed the malady of sufficient severity to require medical advice. A few of the cases to which our attention was called, were complicated with bronchitis, arachnitis, rheumatism, &c. In two cases severe nervous earache was the leading symptom; in one case, periodical neuralgia of the supra-orbital nerve came on every morning at 8 o'clock. Observation soon convinced us that this disease, in the commencement, had its seat in the nervous system, which was in a depressed state, not yielding its normal quota of nervous influence; and that after this, the mucous tissue was the next to suffer. Having succeeded with strychnine in many of these diseases denominated neuroses, in which there was no inflammation or congestion of the nervous centre, we supposed that in this affection its use might be followed with results equally favourable; and we therefore resolved to use the remedy upon ourselves, provided there was an opportunity. With this we were *favoured* about two weeks ago, when, whilst under the influence of mere nervous sedation and irritability, with a commencing derangement of the mucous tissue of the head, we took a full dose of the medicine; and we were happy to find ourselves relieved in a few hours of every symptom. We were soon after called upon by a young gentleman, who was attacked with the prodromic symptoms, to whom we gave a portion, which also cut short the disease. Our next case was that of a female, æt. 50, subject to occasional paroxysms of hysteria. We found her in the chill with violent pains in the head, back, and extremities, accompanied by hoarseness and cough. Gave comp. ext. colocynth grs. x., and blue mass, grs. v., as a laxative, to be aided by sulph. magnesie, if necessary. After the intestinal canal was evacuated, we exhibited the strychnine; and in twelve hours the patient was free from the disease. We have since exhibited this potent nerve in a number of cases with equally good effects, always first subduing any local inflammation which might be present.—*Dr. Gilbert, in New York Journ.*

HERCULEAN TREATMENT OF DYSENTERY.

WE make the following extract from a private communication, dated October 3d, from Dr. P. Fahnestock, of Pittsburgh, Pa.

There has recently prevailed in this vicinity, about two miles from the city, an endemic dysentery, characterized by considerable febrile action, with frequent mucous or bloody evacuations, and violent tormina and tenesmus. It attacked both sexes and all ages indiscriminately, and among them I attended from sixty to eighty cases. As my treatment was peculiar, and as its success confirmed its propriety (but three

cases having proved fatal), I will state how I managed them.

In the case of an adult patient of either sex, having ten or twelve stools per hour, consisting of blood and mucus alone, accompanied with great tormina and tenesmus, I usually gave from six to fifteen grains of pulverised opium, with from xx. to xxx. grs. of calomel; but if the pulse was full and frequent, this treatment was premised by general blood-letting and the application of leeches to the anus. In six or eight hours after the administration of the medicine, I prescribed the following :

R. Ol. Ricini, ʒjss.; Spir. Terebin. ʒss.

These were my maximum doses; and after the operation of the oils, I gave calomel and Dover's powder in small doses, with gum-water as a drink, and rice and arrow-root as diet. It was seldom found necessary to repeat the calomel and opium. To children, six or eight years old, I gave as much as four or five grains of opium, without producing more than a few hours' sleep.—*New York Journal of Medicine.*

HYDROPATHY IN FRANCE.

UPON an application being made to the French Government for permission to open an hydropathic establishment in Paris, the government referred the subject to the French Academy for their opinion. The following are the conclusions to which the Academy arrived, after mature consideration:—"1, That hydropathy is a dangerous therapeutical method, which does not rest on facts; 2, That its theory is chimerical; 3, That it is in discord with our chemical and pathological doctrines; 4, That the Academy cannot in any way approve of it; 5, That the use of cold water has been long in the domain of medicine, and submitted to rules."—*Times.*

Observations on the Proximate Cause of Insanity. By James Sheppard, M.R.C.S.

ACNE INDURATA.

To the Editor of the Medical Gazette.

SIR,

In reply to a "Constant Reader," in your last number, I think he will find Creosote,

administered in doses of one minim three times a day, for some length of time, the best remedy in acne indurata. Combined with this I am in the habit of ordering a lotion of nitric acid locally (ʒss.—Oj.), and enjoining a good nutritious diet, with fresh air and exercise. My success with this plan has been considerable in those generally very obstinate affections, and I strongly advise your correspondent giving it a fair trial.

Your obedient servant,

OBSERVATOR.

Feb. 20, 1844.

P.S.—This remedy was first used for this disease, we believe, by Dr. Elliotson.

ON DISEASES ARISING
FROM THE
DEFECTIVE EXPANSION OF THE
LUNGS IN EARLY YOUTH;

*Being the Gulstonian Lectures at the Royal
College of Physicians, delivered*

By GEORGE HILARO BARLOW, M.D.

Fellow of the College, and one of the Physicians
of Guy's Hospital.

It is, I believe, admitted upon all hands, that the period of early youth is one of the most important epochs in human existence, not only as regards the formation of the character and disposition of the mind, but also the establishment of the health of the body; and also—that a proportionate development of the different organs of the latter is essential to the maintenance of that health.

Yet, although the truth of these two propositions is thus generally acknowledged, still I cannot but suspect that the idea entertained of them is for the most part too indistinct, and that the relation which they bear to each other is too commonly lost sight of; and further, that we are too apt to content ourselves with vague expressions, and consequently with inaccurate notions, respecting the effects of the elaboration of the sexual organs upon the rest of the system, forgetting that they are not the only parts the more perfect development of which may be expected about the period of which we are speaking.

Now, although it cannot be reasonably doubted that there is no part the anomalous development of which (whether excessive or deficient) can fail to produce some corresponding impression upon other organs, the estimation of which should never be omitted when we would calculate the probable pathological results of any such irregular development; yet there seem to occur, at this period, certain general changes in the

proportions of different parts, which must call for compensating changes in the organs of circulation, assimilation, and depuration.

It would, I need hardly say, occupy a far longer time than that allotted for the delivery of these lectures (even if I were in other respects capable of the task), to follow out the subject of proportionate development to the fullest extent; for not only is the subject itself almost unlimited, and one which involves considerations, and suggests questions, in almost every department of physiology and pathology; but, also, is there but comparatively little aid to be obtained from the labours of those who have preceded me. I do not, indeed, mean by this to assert, that no account has been taken by other pathologists of lesions of nutrition, or that hypertrophies, or undue developments of various organs, have not been enumerated amongst these; on the contrary, I rather incline to the opinion, that an almost undue importance has been assigned to them, owing to their having been regarded as primary affections, and not, as I believe more frequently happens, the consequence of some antecedent derangement, generally a suspension of function of some other organ. I shall, therefore, in the course of these lectures, confine myself to the consideration of disease dependent upon a want of proportionate growth between the lungs, the liver, and the two sides of the heart.

Before proceeding further, I would beg to call attention to the circumstance, that the different excretory organs are in a great measure coadjutive and supplementary to each other, which is, I believe, more particularly the case with respect to the lungs and the liver. This is strikingly shown by the fact, that in the different classes of vertebrate animals the liver increases in the same measure that the respiration diminishes; being at its maximum in fishes, at its minimum in mammalia, and having its mean amongst reptiles. Now the fœtus in utero

may be said in this respect nearly to resemble the fish; and, accordingly, we find that its liver is much larger than in extra-uterine life. As childhood advances, and the voluntary muscles are more exercised and more developed, while the portion of time spent in sleep becomes less, there is greater need of the respiratory function. Accordingly, we find a gradual increase in the proportionate development of the lungs, and corresponding diminution of the liver. It is, however, in the period of youth that the change in question seems to be carried out to the greatest extent; for during this period growth becoming less rapid, and consequently nutrition comparatively less active, so, owing to the fuller development of those parts whose blood is returned to the heart directly through the *venæ cavæ*, and the less activity and volume of those which pour their venous blood into the portal system, a proportional change now takes place in the functions and volume of the liver and the lungs, the latter being developed, if I may be allowed the expression, at the expense of the former.

[The lecturer here exhibited diagrams shewing the increase in the ratio of the chest to the abdomen from childhood to manhood, and shewed that although this ratio remained almost stationary between the ages of one and nine years, it nearly doubled between the latter age and manhood.]

When the lungs are sound, the capacity of the chest sufficiently ample, and the air passages of due calibre, this change is effected with safety, and that full expansion of the chest is effected, which, as we may learn from the statues of antiquity, has been at all times regarded as indicative of health and vigour. If, on the other hand, the chest be contracted, or the heart obstructed or embarrassed, or the larynx, trachea, or bronchi narrow or compressed, or the lungs unsound, we should anticipate that one or both of two evils must be the consequence—1st, either the change which should now take place is prevented, the lungs and the liver retaining their original proportion, the result being imperfect respiration, a tumid abdomen, and an ill-developed frame; 2d, or the lungs suffer from the increase of function which they are called upon to perform, which must more especially be the case if there exist in the system a predisposition to tuberculous disease;—or it may happen, though more rarely, that both these evils may concur.

In the first case, the mischief arises through the medium of the pulmonary circulation, which becomes obstructed, thereby giving rise to dilatation of the right side of the heart, with or without hypertrophy, though more commonly the former, the lungs themselves being, at the first, free from structu-

ral lesion. In the second there may be, primarily, no mechanical impediment to the pulmonary circulation, or to the inflation of the air cells; but the lungs become the seat of structural change, at the time that their functional activity should be the greatest. This structural change may no doubt give rise to obstruction on the right side of the heart, and consequent venous congestion throughout the body: still such obstruction and congestion will rarely become a very urgent and permanent symptom, unless the structural change in the lungs have taken place very rapidly.

I now proceed to call your attention to the first division of my subject, namely, pulmonary obstruction, with hypertrophy or dilatation of the right heart.

The cases in which this occurs may, I think, be divided into five classes:—

1. Those in which the obstruction to the circulation in the right side of the heart is produced simply by defective expansion of the lungs and air passages.

2. Those in which it is the result of morbid contraction of the thoracic walls, as pleuritis.

3. Those in which it is the result of pericarditis, acting *mediately* through the impediment opposed to the respiratory movements.

4. Those in which it results directly from the obstruction to the return of the blood to the left side of the heart, produced by contraction of the left auriculo-ventricular opening.

5. Those in which the origin of the mischief is of a more complicated character.

I. In speaking of those forms of disease in which the derangements in question appear to arise primarily in defective expansion of the lungs and air passages, it may be well to trace synthetically the series of derangements which might antecedently be expected to arise from such a cause, and then we shall be able with greater accuracy to investigate analytically the origin of the morbid changes observed in some of the cases of which I shall presently have occasion to speak.

Supposing, then, that about the period at which the more perfect development of the chest may be expected to ensue, the growth of that region of the body is from some cause arrested, what would be the immediate and necessary result?

I believe that in the young subject there would be diminished flow of blood from the right ventricle, with narrowness of the pulmonary artery. The first of these results, viz. the diminished flow of blood from the right side of the heart, appears to be so obvious, and must, I think, be so familiar to all who have had frequent opportunities of

inspecting the bodies of persons who have died of pulmonary obstruction, that it may seem superfluous to adduce any further proof of it. Still, as I have heard the objection urged, that impeded respiration, although it interferes with the aeration of the blood, does not necessarily oppose its passage from the right heart; since, in suspended respiration, blood, though black, continues for some time to be circulated; and further, that the movements of respiration cannot aid the pulmonary circulation, because, forsooth, they are not synchronous with the pulsations of the heart; it may be well to consider for a moment the forces which maintain the pulmonary circulation.

Now I think it will readily be admitted, that the first propelling power is the systole of the right ventricle. By means of this force the artery is filled, and the resistance opposed by its elasticity overcome. As soon, however, as the systole ceases, the valves being closed, the pressure exercised upon the blood in the pulmonary arteries, by the elasticity of these arteries, can act only in propelling it in a continuous current; so that we may regard the heart and large arteries as an apparatus for converting an alternating motion into a continuous one, much as a steam engine with a fly-wheel; or, to use the more appropriate comparison of Sir Charles Bell, the elasticity of the artery acts like the compressed air in a fire engine, to produce a continuous current from a force acting at intervals. In a word, the heart acting mediately through the elastic force of the pulmonary artery, is the propelling force of the pulmonic circulation.

But there are also attrahent forces aiding to maintain the same circulation; of these, I believe that one is mechanical, and the other vital. The first, or mechanical, is the diminution of the elastic force of the air in the lungs which must take place at each inspiration. There must be, it is true, a corresponding opposing or retarding force arising from the compression of the air at each act of expiration, but the effect of this force is counteracted by the closure of the sigmoid valves, so that the respiratory movements act upon the blood in the pulmonary vessels much in the same manner that the pressure of muscular contraction acts upon that in the systemic veins, *i. e.* only in one direction, regurgitation being prevented by the closure of the valves. Hence it follows, too, that whilst the alternate decrease and increase in the elastic force of the air, produced by the expansion and contraction of the lungs, acts as an attrahent force to aid the flow of blood from the right side of the heart, it also acts as a propelling force to return it to the left. I would here beg to remind you, that I am now speaking

solely of the *pulmonic* circulation, and that these remarks, in so far as they relate to the action of respiration upon the circulation, will not apply to the blood in the systemic vessels, the cases being altogether dissimilar, for it is to be remembered that the heart and the origins of the large vessels are, by the dense membranous walls of the mediastinum, excluded, or nearly so, from the influence of the changes in the elasticity of the air, resulting from the respiratory movements of the chest, whilst the ramifications of the pulmonary arteries and veins are left fully exposed to that influence—a condition which does not exist in the systemic circulation.

The other or physiological attrahent force, will, perhaps, be best explained by considering what occurs in other parts.

Now, we observe that if the circulation in any organ be excited to increased activity, the artery supplying that part, or organ, undergoes a corresponding increase. Take, for instance, the case of a diabetic kidney, or of the testes of those animals whose sexual organs undergo a periodic excitement. In both these cases we find an enlargement of the artery, but this enlargement cannot be accounted for upon any simply mechanical principle; for we have an increase in the capacity of the capillaries, as well as an increased flow through the branches of the afferent duct, circumstances which, by facilitating the flow of blood from the artery, must produce a condition of that artery the very opposite to mechanical distension. Again, take the case of an artery supplying an inflamed part, and here we find a similar enlargement under precisely similar circumstances. There is, however, another instance, and one, perhaps, still more to my purpose, in which it is often said, though, I believe, incorrectly, that an artery enlarges from mere mechanical distension. I mean the case of an anastomosing branch, when a ligature has been placed upon the main trunk. Where this has been done, there must, it is true, be produced a slight increase in the distending force of the current from the left ventricle, arising from the blocking up of a large channel; but this effect is felt by all the arteries of the body in common with the anastomoses of that which has been tied, and cannot, therefore, be reasonably regarded in the light of a cause to an effect which is produced solely upon the latter. But this is not all; for one of the first consequences of placing a ligature upon an artery must be the emptying, or nearly so, of that part of the artery beyond the ligature, the effect of which must be to enable the anastomosing branches entering it at that part to empty themselves the more readily, and thereby to diminish the lateral or distending pressure of the blood contained in

them; so that we perceive that in this most notable instance of arteries enlarging to suit the wants of the part which they supply, this enlargement is not the result of mechanical distension, but, on the contrary, takes place, if I may be allowed the expression, in defiance of a diminution of that distension.

Take, again, the opposite case of a change in the condition of any organ diminishing the vascularity of that organ, as in the testes of the animals above alluded to, after the periodic excitement has subsided, or the uterus after parturition, and we find the arteries contracting, although exposed to an increased distending force; the same thing also happens on the cardiac side of a ligature on an artery, between the ligature and the origin of the anastomoses.

This relation, then, between the vascularity of a part and the size of the artery which supplies it, by which the latter increases in a direct proportion with the former, appears to be a law of the arterial system: whether this law operates through the medium of the ganglionic system of nerves, or whether it is brought about by any change in the nutrition of the arterial tunics resulting from alteration in the quantity of blood in the arteries, it is hardly to my present purpose to inquire (though I incline to the former opinion), my object being to establish the truth of the law itself.

Now this law, as we have seen, applies to the glands in common with or even beyond other structures, so that when any such organ is called into greater activity by its natural stimulus being maintained in increased intensity (by which its vascularity is also increased), a corresponding enlargement takes place in the volume of the artery which supplies it—and the converse. Now I believe that physiologists are nearly all agreed in regarding the lung as a gland, of which the pulmonary artery and vein are the afferent and efferent vessels, and the trachea both an afferent and an efferent duct. And accordingly we should expect that under the influence of its natural stimulus, the air, the activity of the pulmonary circulation would be increased, and the calibre of the artery enlarged—and the converse. This agency of the air in increasing the flow of blood through the lungs, and increasing the calibre of the artery, I have classed amongst the efferent forces.

The forces, then, which maintain the pulmonary circulation, are the propelling force of the systole of the right ventricle, and elasticity of the pulmonary arteries; and the attrahent forces resulting from the diminished elasticity of the air during inspiration, and the physiological action of the air, the natural stimulus of the lung, producing a flow of blood to the organ, and developing its afferent vessel. To these may be added the propelling force through the veins of the

increased elasticity of the air in the lungs during inspiration.

We perceive, then, from this view of the forces which maintain the pulmonary circulation, that activity of the respiratory function must have the effect not only of propelling the blood through the lungs, but also of developing the pulmonary artery, and consequently where this function is impeded, we should anticipate obstruction to the passage of blood through the lungs, or, in other words, from the right ventricle, and deficiency in the calibre of the pulmonary artery.

The consequence of the obstruction to the passage of the blood from the right ventricle will be dilatation of its cavity, accompanied (except in debilitated constitutions) by hypertrophy of its walls.

Another effect of a diminished flow of blood from the right ventricle must be an impediment to the entrance of the blood into that ventricle. And it matters little, as far as regards the effect upon those organs which return their blood to the right auricle, whether we assume the current through the right auriculo-ventricular opening to be diminished, or that the blood regurgitates at each ventricular systole; at the same time, I think it probable that the latter is the case, the safety-valve force of the tricuspid valve, pointed out by Mr. T. Wilkinson King, being called into play by the obstacle opposed to the emptying of the right ventricle at its pulmonic orifice. I say it matters little as regards these other organs, for I think the effect upon this part itself would be different in the two cases. If the current through the tricuspid valve were diminished, and no regurgitation took place, I should expect that that orifice would be smaller than in the healthy subject, and that there would be great dilatation of the auricle, whereas in the latter case, that of regurgitation, I should expect to find the auriculo-ventricular orifice would be of full, or perhaps preternatural size; both ventricle and auricle being hypertrophic as well as dilated. There would also, *ceteris paribus*, be more pulmonary apoplexy in the former case than in the latter. The immediate consequence, however, in either case, would be great distension of the auricle, which, being kept up by the pressure of the blood in the veins, dilatation and hypertrophy of that cavity likewise would ensue. This state of the right heart would give rise to distension of the great venous trunks, with accumulation of blood in those reservoirs, if I may so term them, the liver and the spleen; and the secondary consequence, congestion of the whole venous system, with lividity and anasarous effusion. The same cause, also, must produce impeded passage of the blood through the *vena cava hepaticæ*,

and consequently through the portal veins, and thereby cause engorgement of the liver and ascites.

Having now traced the consequences of defective expansion of the lungs through the right side of the heart to the extreme veins, we might, no doubt, continue our course back from the veins, through the arterial system, to the left side of the heart, and we should find that some effects would be produced throughout by the obstruction to the return of the venous blood, and these effects ought by no means to be lost sight of: as, however, there are results of greater importance produced in the opposite direction, we will first return to the lungs, and trace the sequences of diseased action through the left side of the heart into the arterial system.

First, then, it must be obvious that the transit of blood through the lungs being obstructed, there must be a diminution in the quantity of blood returned from the lungs to the left side of the heart; the effect of this will be a smallness of the auricle, and as I believe that not only the arteries, but also the orifices of the different cavities of the heart, adapt themselves to the quantity of blood transmitted through them, we should expect, at the same time, to find a narrowness of the left auriculo-ventricular opening.

In the same way we should infer that the capacity of the left ventricle would be small, its walls probably thin, and the aorta narrow: from the same cause, namely, the small quantity of blood passing through the left side of the heart, the calibre of the arteries would be small throughout the whole of the body likewise. Such, if I mistake not, would be the effect produced directly upon the left heart and arterial system, by defective expansion of the lungs.

But, as I have before stated, some effects must also be produced upon the left side of the heart by the venous obstruction already described, which must be brought about as follows: the obstruction opposed to the onward current of the blood in the veins, and the ultimately congested or even indurated condition of several parts through which the circulation has to be maintained by the left ventricle, must tend to embarrass that ventricle, and thereby induce in it dilatation, or dilatation with hypertrophy, so that there would be two opposite causes in operation: 1st, the diminished flow of blood into the left ventricle, which would have the effect of diminishing the cavity of the ventricle, and thinning its walls; and 2dly, the venous obstruction, which would have the contrary effect: so that accordingly as one or the other course might preponderate we should expect to find a corresponding state of the left side of the heart.

The morbid changes, then, which upon the principles already laid down, we should ex-

pect to find associated with defective development of the lungs and air passages, would be, in extreme cases, narrowness of the pulmonary artery, dilatation with hypertrophy of the right ventricle and auricle, with the same conditions, though in a far less degree, on the left side of the heart, and narrowness of the aorta; engorgement of the great venous trunks; enlargement of the liver and spleen, with nutmeg degeneration of the former, leading to contraction and induration in the more advanced cases; ascites; general venous congestion; and anasarca.

These, I believe, are the morbid appearances that will most commonly be found, although there can be no doubt but that others will arise in the progress of so long a series of diseased actions as those which have been described; neither can it be doubted, that such lesions, however produced, must, when established, modify to a great extent the effects produced upon various parts by the primary derangement. These complications will, however, be best understood by a reference to the particular cases in which they were observed.

The following is a good though rather an extreme instance of the uncomplicated cases.

CASE I.—In the summer of 1827, Mary Kendal, aged 12 years, became my patient at the Surrey Dispensary. She had been for some months previously under the care of Mr. Turner, of Bermondsey Square, who kindly informed me that she had been affected with dyspnoea and palpitation, with symptoms of enlargement of the heart, and there had been manifest peritoneal effusion. Her health was stated to have been good during childhood. She was of moderate height for a person of her age, and her limbs were well formed and straight, without any tendency to rachitic distortion. The chest, however, appeared small in comparison with the abdomen, as far as I could judge, in the distended state of the latter. There was extensive dullness on percussion over the region of the heart, where a hoarse systolic murmur was distinctly audible: the liver was to be felt distinctly about an inch below the margin of the ribs; and there was considerable effusion into the peritoneal cavity. The jugular veins pulsated considerably, and her countenance was slightly livid. The pulse small and frequent. Her urine was dark, and became turbid on cooling, but contained no albumen.

She was greatly relieved by local depletion, moderate purgatives, and diuretics, combined at first with mercury. At the end of a little more than two months she was free from all dropsical effusion, and was able to walk gently for more than a mile.

During the course of the three following years she had occasional returns of the symp-

toms already described, which yielded to purgatives and diuretics. In May, 1840, she again became my patient, her symptoms being the same as when I first saw her in 1827, with, however, greater severity. She was now 15 years old, and I remarked that she had grown scarcely at all during the preceding three years, which observation was confirmed by her parents. Her extremities, however, appeared small in comparison with the trunk. There was now dulness on percussion over a large space in the cardiac region, which extended considerably further to the right than we find to be the case in healthy subjects. A double bellows sound was distinctly audible, and loudest at nearly an inch to the right of the sternum. The resonance of the chest was slightly, though very slightly, less than natural, excepting at the space just mentioned, and the lower part of the right side: the respiratory sound was generally good, though not audible below the seventh rib on the right side, owing probably to the enlargement of the liver. The countenance was livid. There was considerable peritoneal effusion and œdema of the legs. The urine was scanty and high coloured, depositing a reddish brown sediment. Tongue furred, with red edges and prominent papillæ.

It would occupy far too much time to follow the progress of this case more minutely. Suffice it therefore to say, that relief was again obtained, chiefly, as it appeared to me, by means of diuretics; she, however, speedily relapsed. Obtained temporary relief from paracentesis abdominis, and died on the 28th of March, 1840, four years after she first became my patient, and nearly five from the commencement of the disease.

Upon examination of the body 24 hours after death, the following appearances were noticed.

The stature was short for the size of the subject, and the extremities small for the size of the trunk. The chest appeared narrow and ill developed. The mammae and external genitals infantile. When the abdomen was opened, the liver was seen to be enormously enlarged, and its acute margin blunted. The omentum thickened and contracted. The peritonæum generally dark, and rather opaque; it contained about three quarts of pale straw-coloured turbid serum. The liver when cut into was very hard, and presented the character of the nutmeg degeneration in its most advanced stage. The right kidney was large and healthy, evidently a very active organ; the left was smaller, but otherwise resembled the right.

Upon raising the sternum and cartilages of the ribs, little was brought into view but the distended pericardium, which extended on the right side beyond the space thus exposed. The pericardium contained a small quantity

of clear serum. The right auricle and ventricle were enormously distended; the latter formed the apex of the heart, and before it was opened was larger than a large man's fist. The left side of the heart was large, but appeared small in comparison with the right.

The right auricle was found to contain a large and rather loose coagulum; its cavity was very capacious and its walls much thickened. The auriculo-ventricular opening when viewed from the auricle appeared to be about an inch and a half in diameter. The cavity of the right ventricle immensely exceeded the natural size, and its walls were hypertrophied. The chordæ tendinæ were tense, so that it was impossible for the tricuspid valve to act perfectly; but setting this aside, its curtains were manifestly inadequate to close the orifice. The valve was structurally healthy. The orifice of the pulmonary artery was small, as was also the artery itself; its sigmoid valves were healthy. The left auricle and ventricle were dilated, but in a much less degree than those in the right side; their walls were hypertrophied. The aortic sigmoids were perfect; the aorta very small, but otherwise healthy. The anterior portion of the upper lobe, and anterior and inferior portion of the middle lobe of the right lungs, were pale, exsanguine, and but slightly crepitant; this condition being obviously the effect of compression by the right auricle. The posterior portion of the lung was congested, the anterior firm, and but feebly crepitant, as if from compression. The upper lobe of the left lung was healthy, the lower much in the same condition as the corresponding one on the right side. The trachea was very small throughout, and there was a manifest narrowing about an inch and a half above the bifurcation; both bronchi were compressed and flattened.

Upon comparing the history of this case, as well as the appearances observed on inspection after death, with the chain of functional derangements and organic changes, which, as I have been endeavouring to shew, we should expect *à priori* to result from defective expansion of the lungs, we shall at once perceive that they are nearly, or I may say, entirely identical. We are therefore, I think, justified in assuming that such defective expansion, when it exists, is capable of producing the disease which was here observed; but as there is a tendency amongst pathologists, or I should rather say amongst morbid anatomists, to assign as the primary lesion that which is most notable and obvious, it may be well to inquire whether this might not have been a simple case of hypertrophy of the right side of the heart. Now, if I mistake not, it would be very difficult to shew how an increase in the size and strength of the right ventricle could cause a delay in

the pulmonary circulation, impede the development of the lungs, and cause a narrowness of the trachea; and, further, that there is every reason to doubt, or even to deny, the existence of such a thing as idiopathic and primary hypertrophy of the muscular parietes of the heart in any case; for it is contrary to the analogy of other muscles to find an increased development independently of increased activity, whereas continued and increased activity is always followed by a corresponding increase of nutrition. And, as regards the heart itself, we always find, excepting in very debilitated subjects, that any persistent cause of obstruction to the flow of blood from one of its cavities is always found attended by hypertrophy of that cavity, whereas I am acquainted with no instance of hypertrophy without some source of obstruction or excitement.

Congenital narrowness of the pulmonary artery might indeed be supposed capable of producing many of the results which were here observed; but the structure of that artery was perfectly healthy; and without strong proof to the contrary, I am much inclined to disbelieve the existence of such a thing as an artery, whose tunics are naturally healthy, being too small for the current of blood which it is intended to convey, such a disproportion being at variance with that of the adaptation of the size of an artery to the part supplied by it, which we have already noticed.

There was one remarkable exception to the narrowness in the orifices of the heart which was observed in the above instance, namely, the great size of the right auriculo-ventricular orifice. Now, if we suppose that the right ventricle had no means of emptying itself but through the pulmonary artery, we shall be at a loss to understand how this could have been effected without the infliction of severe injury either upon the pulmonary artery or upon the lungs themselves; but owing to the salutary imperfection of the tricuspid valve, a large quantity of the blood which had entered the ventricle was, at each systole, got rid of, and thrown back into the great venous trunks through that valve. Thus, then, we find, in this remarkable exception to the general condition of the orifices of the heart, an additional proof of the safety-valve function of the tricuspid valve, pointed out by Mr. King, and also a reason for the absence not only of pulmonary apoplexy, but also of any injury of the tunics of the pulmonary artery.

Another inquiry which suggests itself, in regard to the etiology of this and similar cases, is whether the diminished capacity of the chest might not have been the cause of the defective expansion of the lung. Now it appears agreeable to the analogies to be drawn from other parts of the body, to sup-

pose that the softer and more important structure gives form to the harder and less important, rather than the harder to the softer, as the skull is indented by the convolutions and vessels of the brain, and bone is absorbed before the pressure of an aneurismal tumor; and, accordingly, the bones of the chest, provided they are healthy, and not the subject of rachitic or other disease, adapt themselves, in form and capacity, to the viscera which they are required to contain; so that, although rachitic distortion, or other diseases of the osseous system, as well as the contraction of false membrane effused in pleuritic inflammation, may, by compressing the lungs, give rise to disease resembling that which I have been describing, still in this, and similar cases, where the bones appeared well formed, and where there was no disturbance from any other cause, it is more probable that the small capacity of the chest was the effect of the diminished bulk of the lungs, than that the converse was the case.

Again, are we to regard the smallness of the trachea as cause or effect of the diminished capacity of the lungs? Now this is a question which, I think, we are at present hardly in possession of facts enough to enable us to answer. We should certainly be inclined, *à priori*, to expect that the size of the duct would be dependent upon the size and activity of the gland, rather than that the contrary would be the case; but in speaking of the lungs and trachea, we should remember that the trachea is not the mere efferent duct of the lungs, but it is also the afferent duct by which atmospheric air, which is necessary for the performance of their function, is conveyed to them; so that, regarding it in this light, we should suspect that the size of the trachea would materially affect the development of the lungs; and it has been ascertained, as in the case of the monkey quoted by Dr. Stokes from Reynaud, that obstruction of a bronchus causes atrophy of the lung to which it leads; but, on the other hand, some cases which I shall have occasion to notice hereafter seem to show that the trachea is small where there seems to have been a defective expansion of the lungs from causes acting more directly upon them than upon it. Upon the whole, then, without further data, I think that we must regard the lungs and large air passages as one entire apparatus, the different parts of which are developed proportionately to each other.

Now it is worthy of notice, that the patient whose case we have been considering lived in a narrow, ill-ventilated, and ill-drained lane in Bermondsey. She was therefore exposed to a disagreeable atmosphere, loaded with the nauseous exhalations from drains and tan-pits, which

would impede the exercise, and consequently check the development, of the respiratory apparatus; and, further, these exhalations, being the products of the decomposition of organic matter, would, if absorbed into the system, be prone to pass out of it by the liver and kidneys, and consequently act as stimulants to those organs; so that there was a two-fold agency in operation, tending to repress the activity of the organs of respiration at the same time that it excited that of the auxiliary excretory organs—the liver and the kidneys; the effect of which was manifest as well during life as after death. Of the liver it may be true that its disorganization depended more upon mechanical than physiological causes; yet it is probable, from the state of the evacuations, that at an early period it was a highly active organ; for it was obviously enlarged when I first saw the patient in 1837: yet she was not observed to be at all jaundiced till March 1841; whereas it is probable that, had the liver been mechanically distended, a condition which would have checked its action as a secretory organ, some tinge would have been observed at an earlier period. Of the kidneys there can be no doubt that they were in a state of great activity till near death; and it is to this circumstance that the relief which was often afforded to the patient was in a great measure attributable. It should be observed, that although this patient lived surrounded by the causes which excited the original disease, and must therefore have tended to excite it, she was in other respects under favourable circumstances, not having been subject to privation or exposure, and not called upon to make any excessive exertion; so that the absence of any of those complications which such disturbing causes would probably have excited, allowed the primary affection to develop itself to the fullest extent.

ON

DIFFERENT FORMS OF GRANULAR DISEASE OF THE KIDNEY.

By J. D. HEATON, M.D.

[Continued from page 683.]

(For the *London Medical Gazette*.)

ANN COX, aged 57, admitted under Dr. Thompson, June 28, 1841. A widow, the mother of nine children. She has a very emaciated appearance, with an anæmic, sallow complexion. She has been deserted by her husband, who has left her in great destitution for the last twelve months; she denies having been intemperate; has previously had good health.

About nine weeks ago, she had an apoplectic stroke, which came on quite unanticipated; she was deprived of consciousness for some minutes, and the left leg was paralysed for two days, after which she regained the use of it. Soon after this, the legs and feet became oedematous, and the abdomen is stated, also, to have been dropsical. She had great oppression of the breathing, and a sensation of suffocation. No observation was made as to the state of the urine at this time. The patient received medical treatment, but without benefit. For some weeks she has been almost quite unable to lie down, from the great dyspnoea caused when she is in that posture.

At present, great debility and dyspnoea, amounting almost to orthopnoea, rarely allowing her to lie down, are her chief complaints. She has a sensation of sinking at the epigastrium, and much depression of spirits. She has headache; the intellect seems dull and oppressed. There is an aching pain in the loins. Tongue rather brown, almost dry; bowels active; abdomen rather tender, not distended. Pulse frequent, small, and sharp, the pulsations being very visible at the wrist. The arms and legs were marked with numerous small, dark-coloured petechiæ, of the nature of purpura. The feet very cold; the legs and thighs highly oedematous, but no dropsy of other parts. Extensive dulness of stroke-sound over the cardiac region; sounds of the heart obscure; each sound is accompanied with a murmur. Respiratory sounds healthy. Urine scanty, of a natural appearance, but depositing albumen copiously on adding the usual tests; sp. gr. 1015.

R Sodii Chloridi, gr. x.; Quinæ Disulph. gr. ij.; Acid. Hydrochlor. dil. M. vj.; Infus. Cascariæ, lb. ss. M. ft. haust. ter die sum.

On the 30th, the tongue was less brown, and there appeared rather more activity of the mind; but other symptoms were not much changed.

Fiat Haustus c. Sodii Chloridi, ℥j.

R Pulv. Digitalis, gr. j.; Ext. Gentian. gr. ij.; M. ft. pil. 8vâ quaque horâ sumat.

July 2d.—The patient has sunk into a state of low muttering delirium, scarcely conscious of anything that is said to her, but talking unconnectedly to herself. She has complained of pain in the loins, which part seems tender on pressure. Pulse 108, rather resisting; tongue dry and adhesive. Legs oedematous as before. Urine very scanty, and highly albuminous.

Repetantur Pulveris. Omitte Misturam.

R Potas. Bicarb. ℥j.; Infus. Diosmæ, ʒiiss. M. ft. haustus ter die sumendus.

5th.—The patient is in a constant doze; gives no answers to questions, but will put the tongue out when desired. The urine is passed involuntarily, but very scantily. Pulse 100, very small and feeble. Tongue moist and glazy. She takes nothing but wine and water.

Omitte medicamenta. Habeat Vini, ij. quotidie.

9th.—The patient had been in a state of almost continued sopor since last report, till yesterday evening, when she suddenly aroused from the soporose state in which she previously was; her senses returned, and she sat up in bed, and appeared rational and collected. At the time of this report she answers questions readily, though in rather a wandering manner. She is craving for food, having eaten nothing for some days till this morning, when she had a large mess of arrow-root, with wine and bread. She has passed about two pints of urine in the ordinary manner, rather dark, depositing a flocculent cloud on standing, but not containing a trace of albumen—sp. gr. 1013. The tongue is moist, quite clean, but glazy and rather adhesive. Pulse 88, small and feeble, but its movements very visible. In addition to the dropsy of the legs, the face has now become oedematous on the right side.

12th.—The patient has sunk into her former state of sopor; the pulse has risen again to 100, but is very feeble. The tongue quite dry; face very oedematous. Bowels have not been moved for two days.

Statim Sumat. Ol. Ricini, ℥ss.

13th.—The patient died this afternoon, being in a comatose state before death.

Sectio cadaveris, post-mortem horas xxii.

External appearances.—The body is much emaciated, and had a sallow, bloodless appearance. On the inner sides of the arms and legs were petechiæ of a dark red colour and irregular form, most of them being small, and in irregular groups, a few on the thighs isolated, and of the size of a sixpence. The arms were not at all oedematous, but the whole of the lower extremities very much distended with serum; there was much œdema of the right side of the face.

Thorax.—On opening the chest, about a pint of serum escaped from each sac of the pleura. There were no inflammatory appearances of the serous surfaces, with the exception of some fine vascularity posteriorly on each side. The lungs were rather compressed by the fluid, but were quite crepitant, and had a healthy appearance. On cutting into them, a great quantity of frothy serum oozed out. The pericardium contained about 3ij. of serum. Towards the base, both on the heart and on the inner

surface of the pericardium, was a granular deposit of lymph, of a pink colour, thin, and apparently recently deposited, but forming no adhesions. The left ventricle was dilated and much hypertrophied; the outer walls, towards the middle, were about half an inch thick; the musculi papillares of the mitral valve much enlarged, their apices indurated and degenerated into a fibrous structure; the laminae thickened and contracted; the aperture did not deviate much from the natural size. The right ventricle not much altered from its natural appearance, but the right auricle as well as the tricuspid orifice much dilated. There was some thickening of the aortic valves, a little within the free margin, and the adjacent borders of two of the valves were adherent. The heart weighed seventeen ounces.

Abdomen.—There was no serum in the cavity of the peritoneum. This membrane appeared quite healthy and free from marks of inflammation except over the liver, where it was rather thickened and opaque, but without adhesions. The liver was small in size, but appeared healthy; the gall-bladder was much distended with dark viscid bile, and all the viscera in the neighbourhood were tinged of a dark colour by the exudation of the bile. The liver weighed lb. ij. 7 ounces. The mucous membrane of the stomach presented large patches of dark punctiform redness. The duodenum contained much dark bile of a similar appearance to that in the gall-bladder. The spleen appeared healthy; it weighed 5 ounces. The splenic artery was indurated by a calcareous deposit of white opaque patches, and rings, so as to form an unyielding tortuous tube. The kidneys both presented a very similar appearance. Each was much contracted. When the capsule was removed, the surface underneath was granular or tuberculated, but not very even, the granules being of uniform size. The colour was a deeper red than is usual in this disease; the substance was hard, but brittle. The cortical structure was much diminished, forming only a thin layer around the cones of the tubular structure. The tubuli were quite distinct in the pyramid, and did not appear to be invaded by the morbid deposit. There was a small serous cyst in the cortical structure of the right kidney. Each kidney weighed 2½ ounces.* The bladder was much contracted; it contained from three to four ounces of dark coloured urine.

Head.—On removing the dura mater from the hemispheres, the two layers of arachnoid were found to be adherent along each side of the falx major; in some parts by fine fibrous cords, varying in length from half an inch downwards; in other parts

* Models of these kidneys are preserved in the museum of University College.

closely united. There were no adhesions in other parts, but the arachnoid had a rather milky opalescent appearance. The large veins on the surface were distended with very black blood; but there was also much fine vascularity in the intervening spaces. On removing the brain, a small quantity of serum was found at the base. The substance of the brain was very soft, and in removing it, the lateral part of the right hemisphere gave way, and a considerable quantity of imperfectly clotted blood ran out from the laceration. Farther examination showed that both lateral ventricles were filled with dark blood to the amount of three or four ounces altogether. The cerebral tissue around was completely broken up and disorganised, being reduced to a soft pulpy mass, of the consistence of thick cream, of a pale yellow colour, most extensive on the right side. The optic thalami and corpora striata, were quite destroyed; the septum lucidum was broken up. All the cornua of the lateral ventricles were filled with blood, which likewise penetrated into the third and fourth ventricles, and externally on the surface of the medulla oblongata all the parts of the brain appeared softer than natural, and the cineritious part pale, and of a dirty white colour. There was no bad or gangrenous odour in any part of the brain. All the arteries at the base, and their larger ramifications, were much diseased, being rendered extremely fragile by irregular patches of opaque friable matter deposited in their coats.

In addition to the disease of the kidneys, the concomitant disease of the brain gives to this case much interest, of which, however, in a great measure, it would have been deprived, had the post-mortem examination been omitted.

The history of the case previously to death is such as frequently presents itself in connection with granular disease of the kidneys. The comatose symptoms which preceded death are those in which this malady frequently terminates, and might be regarded, as has been already stated in a previous contribution, as the result of the poisonous effect upon the system of urea not excreted. The sudden disappearance of the comatose symptoms for a time, a few days before death, was certainly remarkable, but occurring, as it did, in connection with a much increased discharge of urine (which, even though free from albumen, had a specific gravity of 1015, shewing a considerable impregnation of urea), I had been induced, in my own mind, to refer it to this temporary removal of much of the poisonous principle from the blood. But, when the examination of the brain disclosed such extensive disease, and of parts of this organ so important and central as already described,

and which, from its appearance, we cannot but suppose to have existed for a considerable time, we wonder how this would be compatible with the amount of sensation and volition, and indeed, in some degree, of the higher mental powers, as must have co-existed with it. Had the parts of one hemisphere alone been affected, the case would have been less remarkable; but both were very considerably diseased, though not to the same extent. The softening of the brain is, in itself, sufficiently intelligible, occurring in connection with extensive disease of the arteries, incapacitating them for carrying on an effective circulation through that organ. It presented that yellow appearance—without vascularity, and devoid of the foetid smell of gangrene—frequently met with around large extravasations, and in connection with disease of the nutrient arteries. It is that sort of softening which Abercrombie supposes analogous to dry gangrene of the leg from disease of the arteries; and quite different from the softening the result of inflammation, and accompanied with the putrid odour of gangrene. The apoplectic fit, and the extensive extravasation which was found in the brain, also receive a ready explanation from the disease of the arteries. Perhaps the vessels were first ruptured, and some extravasation took place at the time of the fit; but we should suppose that the hæmorrhage must have been then of comparatively small amount, and there must have been a gradual oozing of blood since; for so extensive a discharge of blood into the substance of the brain occurring suddenly must have proved immediately fatal. The adhesions between the layers of the arachnoid were remarkable; they were evidently of long existence, and not the result of recent inflammation. Adhesions between the opposite layers of arachnoid are, I believe, not common under any circumstances; but the existence of *bands* of false membrane, of an appreciable length, between membranes in close apposition and incapable of motion, appears very unaccountable, and is what I have never met with in any other case, either described or at which I have been present. The impossibility of motion in the parts contained within the cranium renders it very difficult to explain the formation of these bands; they were very numerous, most of them short and fine, and connected in groups, but some of them were isolated, and nearly half an inch in length. Perhaps the most probable supposition is, that an inflammatory adhesion had taken place between the two serous surfaces at this point, in infancy, and that a serous effusion had afterwards intervened, and drawn out the lymph into these bands, while the skull was yet

sufficiently yielding to allow of this distension without producing fatal compression of the brain.

The other points to be noted in this case may be briefly discussed. Previously to the supervention of the comatose symptoms, the case presented the characters of an ordinary uncomplicated case of granular disease of the kidneys. The urine was scanty in this instance. The amount of watery fluid which may pass through the kidneys varies very much in this disease; frequently, in old cases, it is more than natural: in this case, as in many others, it was much below the average quantity; but in all it presents a deficiency of its natural ingredients, and generally, perhaps always, at some stage of the disease, it is marked by the presence of albumen. The form of dropsy peculiar to this disease is that of the cellular tissue; where effusion into the serous cavities takes place, it is generally either inflammatory or depends on concomitant disease of other organs. In this patient there was no ascites at any time; a considerable quantity of serum was found in the chest after death; but as an examination had been made during life without any signs of this being discovered, it is probable that this effusion occurred only towards the close of life. So also with regard to the inflammation of the pericardium, which appeared to be quite recent, and had produced none of the usual symptoms of pericarditis during life. The heart was hypertrophied to almost double its natural weight, the left ventricle being the principal seat of the enlargement. The old disease of the valves, and likewise the very diseased state of the arteries, would account for the hypertrophy, which, on the other hand, would itself greatly increase the danger of rupture of the vessels.

The kidneys presented the ordinary appearances of a rather advanced stage of granular degeneration, the contraction and atrophy being, however, principally confined to the cortical tissue, the tubular part being not much affected. With regard to their dark colour, Christison remarks, that when the kidneys are much contracted, the proper brownish tint is often found present; and it is in kidneys where the disease is less advanced that the pale brownish yellow colour is observed. The present instance corresponds very well with this observation, though I have seen other cases which did not so; and it seems difficult to account for this return of colour in connection with the increasing contraction, which produces an increasing atrophy of the natural tissue, and presents, to the entrance of the red blood, an increasing obstacle. Probably, from the first, there is something different in those cases which present this dark appearance of the kidneys in the post-mortem examination.

CONTRIBUTIONS

TO

ANATOMY AND PHYSIOLOGY.

BY ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

[Continued from p. 610.]

On the Corpus Luteum.

WHILST inquiring into the history of the corpus luteum in woman, my brother suggested that a re-examination of some points in the anatomy of the same body in the ewe, cow, &c. might lead to useful results. The following remarks were the result of this inquiry. Aware of the vast influence of specific differences, I have done my best to avoid all forced analogies; the corpus luteum is a structure of an unknown intimate nature, and of an unknown function, whatever may be said to the contrary. To me it appears to belong to the embryo, or at least to the ovum; an intrinsic not an extrinsic part; it probably slightly resembles in function the placenta, which it precedes; it represents the calyx of the ovum (fecundated or not) which has left, or is about to leave, the ovarium; with this important difference, however, that as found in mammals it is a rudimentary structure connected with the transient existence of a node of growth peculiar to the reptile and the bird; the vitelline and allantoid development, or growth, which in man and in mammals is fleeting, momentary as it were, and rudimentary. This theory may, no doubt, be expressed otherwise, for it simply amounts to this—the law of unity, as regards the embryos, includes the rudiments and elements of all nodes of embryonic growth; in this respect all start at first from the same point, and with corresponding or even strictly similar parts. But according to the species must the mode of growth or development differ: let us say that these modes of growth are, 1st, vitelline; 2d, tubal; 3d, uterine and placental: in the bird, fish, and reptile, we have specimens of the vitelline development; in the marsupialia perhaps of the second, and in man and in the mammals, strictly so called, of the third, or uterine, strictly, and placental. But as all sprung from an egg, or ovum, so the vitelline stage of development must exist in all,

however brief the period may be. Thus in man, the vitelline period, confined to a few days, is probably passed wholly within the ovarium, to be succeeded rapidly by the placental mode of existence; whilst in the bird, and fish, and reptile, the embryo, extruded from the parent, depends wholly on, and exists wholly by, its vitelline structures.

Thus it happens that in the ovaria of the more complex forms of animal existence we find the remains of rudimentary structures whose functions, if they really performed any, were necessarily fleeting. The fallopian tubes of woman have been called oviducts; in one sense, no doubt, they are so, but still the term is a vicious one, and calculated to mislead, if the persons who give to these tubes such terms really propose comparing them to the oviduct of the bird, fish, or reptile. The fallopian tubes are strictly uterine parts, and not mere oviducts. The ovum passing along these tubes is totally unlike the ovum of the bird on its way through its oviduct; the one carries with it the whole materials for its vitelline existence, the other has abandoned these in the ovarium. A very small portion of the extremity of the fallopian tube may be likened to a real oviduct, but nothing more; the greater part of the tube is strictly uterine.

Between the bird and man, representing the two extremes of vitelline and placental existence, there are probably intermediate links, but they have not been satisfactorily made out. The uterine existence of the embryo may be shortened, or even wholly left out; but this reminds me that I anticipate what it is my intention to explain more fully in Part V., in which I hope to be able to examine the various theories proposed as to the functions of the corpus luteum: in Part VI., the history of the development of the placenta and its uterine connections will be carefully inquired into*.

PART III.

On the Corpus Luteum in Brutes.

Taking it for granted that the lecture on generation delivered by Sir Everard Home contains many of the

facts made out on this subject by John Hunter, and that the engravings illustrative of that lecture were from dissections made by Hunter, we have gone over the lecture with the greatest care; and with a view to get at the truth and the facts ascertained, we shall confine our attention in this, our third Part, to what is stated with regard to the evolution of the ovum in the lower animals.

Sir E. having alluded to the importance of the subject, and mentioned that Harvey had completely failed in elucidating any thing in the inquiry, makes the following observation with regard to Mr. John Hunter. The subject "became deserving of the consideration of J. Hunter, who has left us, in his collection, a series of preparations shewing the state of the womb on almost every day after impregnation had taken place in the ewe; but his experiments were attended with no better success than those of his great predecessor—Harvey."

In another passage Sir E. states, "De Graaf, Kirkringius, Haighton, and Cruikshanks, were confident that ova were to be met with in all sorts of females, but by mistaking the formation of the corpus luteum for the effect of impregnation, which at that time was an error generally adopted, and, what is sufficiently singular, now, in 1840, universally acted upon and believed, they got entangled in theoretical opinions, that misled them in their future inquiries, and rendered such parts of their statements as were true unsatisfactory."

"The corpus luteum, from its appearances, seems to be entirely a new formation, distinct from that of the ovarium itself; it is always met with in the substance of the ovarium (?) not in the cells (Graafian vesicles ?)" "In its increase it compresses the parts surrounding it so much that when of its full size, and even where there are several in the same ovarium, that body (organ) is not much increased beyond its natural dimensions."

We will have occasion to shew that this is by no means the fact, at least in the ovaria of the sheep and cow. Even in woman, as we have shewn in Part I. of these Contributions, the difference in size and weight is considerable.

"The structure of the corpus luteum is of a very particular kind, and is not distinctly seen in small animals, or

* The whole of the following part was drawn up by my brother, Mr. F. J. Knox.

those that have numerous litters; but in the cow, which commonly has only one calf at a birth, the corpus luteum is so large that when it is magnified the structure can be made out."

The intimate structure may certainly require a magnifier to make it out, but the anatomical arrangement of its parts may be seen with very ordinary sight without the aid of any microscope.

"It is a mass of thin convolutions, bearing a greater resemblance to those of the brain than of any other organ."

We feel rather inclined to compare it to a glandular structure.

"Its form is an irregular oval, with a central cavity."

Most unquestionably there is not the slightest appearance of a central cavity in by far the greater number which we have examined.

"And in some animals its substance is of a bright orange colour when first exposed."

Reference is here made to plate 112. This plate represents, at figs. 1 and 2, ovaria of a cow at two months old; and figs. 3 and 4, fourteen days after impregnation. The ovaria externally present the appearance of numerous Graafian vesicles, but not the slightest appearance of corpora lutea, either externally or on the section: the sections shew numerous Graafian vesicles cut across, and here and there appearances of blood-vessels. We would remark, that the whole history of the engraving should be given, as most assuredly the *recent* ovary, when cut across, never presents the appearances delineated in the plate.

"Corpora lutea are found to make their appearance immediately after puberty, and continue to succeed each other as the ova are expelled, till the period arrives when breeding no longer goes on.

"As the object of these observations is to prove that corpora lutea are the glands formed purposely for the production of ova, that they exist previous to, and are unconnected with, sexual intercourse, and when they have fulfilled their office of forming ova, are afterwards removed by absorption equally, whether the ova are impregnated or not."

Reference is here made to plates 108, 109, 113, 114. Plate 108 represents the embryo (a large human fœtus), exposed by laying open the

ovarian cyst which enveloped it. This reference appears to us singularly and amusingly unfortunate, as by it one might be led to suppose that not only the ovule but a completely developed fœtus may be formed in the human virgin ovary. But in fact, of the plates referred to, it is evident that 113 and 114 are the only two connected with the remarkable and important passage in the text. 113 are (is) the ovaria (ovarium) of a cow *unimpregnated*. The external view, fig. 1, shews the appearance of Graafian vesicles; fig. 2, a longitudinal section; and fig. 3, a transverse section of a corpus luteum. Now, in the first place, we should say that the ovarium represented can scarcely be the one containing the corpus luteum, as when this body is present the form of the ovarium becomes greatly modified by its presence. In the second place, the delineations of the sections themselves most assuredly do not resemble strictly the corpus luteum as seen by ourselves. There is scarcely even an attempt made to shew a central cavity, and in which there should, to correspond to the description, not only have been a central cavity, but an ovum in it.

"The cow is considered to arrive at puberty at two years old. I have, however, met with the instance of a calf within the year having bred.

"In the hog, the age of puberty is six months, although at four months the ovaria are not found to have any appearance of incipient corpora lutea. At five or six months, several corpora lutea have made considerable advance."

A reference is here made to plates 113 and 114. Now, 113 refers to the ovum of the cow; but 114 is clearly the plate alluded to in the text. There is represented at figs. 1 and 2, ovarium and its section of a sow four months old; figs. 3 and 4, ovarium and section before six months; and figs. 5 and 6, ovarium and section at full six months (*i. e.* in a sow six months old.) This plate is a very satisfactory one; both the external views and their section exhibit the appearance of numerous Graafian vesicles, more particularly in No. 2 (that is, at four months); in No. 3 the vesicles are less distinct and fewer, whilst here and there are represented sections of the corpora lutea. No. 6, the vesicles are still fewer in number, whilst six corpora lutea appear to have engrossed nearly the entire

ovarium; there is one large vesicle near the surface. The only remark we have to offer is, that these corpora lutea bear an extraordinary resemblance to the human structure; but what is to be particularly noted is, that they resemble the human when the structure must be presumed to be on the decline, *i. e.*, at the second, third, fourth, or fifth month after impregnation.

"In another virgin sow, nearly six months old, we were so fortunate as to detect corpora lutea in the act of bursting for the expulsion of the ova."

If our author had only given the fact—we mean, if he had made a dissection and found the ova—the proof would then have been complete. Without this proof, the observation goes for nothing.

"It is decided by this proof that females part with ova whether there is sexual intercourse or not, and with such force that the cavity of the corpus luteum is absolutely inverted, so that the ovum is completely exposed to the semen of the male. The extravasation of blood in rupturing the ovary, and inverting the corpus luteum, is in many instances so great, that some of it passes through the vagina, which, when met with after the female has had the male, is considered as a proof that impregnation has taken place. As soon as the ovum is expelled, the corpus luteum recovers itself and regains its former state."

We have thus extracted with the greatest care whatever observations bear on the subject as connected with the lower animals.

That Mr. Hunter's observations and theories were mostly drawn from observation and experiment on the lower animals is sufficiently clear. And as it is also unquestionable that most of the present existing theories on generation and its phenomena are based on the few original facts made (would that they had been also promulgated) by John Hunter, we shall confine our observations in this (Part III.) to an examination of the subject in the lower animals.

January 12th. — Of a number of sheep slaughtered for the market the uteri of twelve were sent me. The sheep were all about twenty-one months old, and were called gimmers by the practical man. They had been kept as carefully from the male as possible, as they were

not intended to breed. It was admitted, however, that in the autumn a tup may have got amongst them, and a few, therefore, might be with lamb.

Dissection.

The uterus externally presents no peculiar appearances, and is of a dark yellowish hue. Upon laying open the uterus throughout its whole length, we find no appearance of vascularity, or any contents. There are numerous little mammillary flattened eminences, the spaces of most of which are coloured of a distinct inky black.

Each of the ovaria presents the appearance of large prominent glandular looking bodies, with numerous vesicles (Graafian?). The glandular bodies assume, invariably, the appearance and position as represented in the figure No. 1, when floated in water or spread on a flat surface. The fimbriated margin of the uterine (fallopian) duct passes from the external pole of the ovary, and sweeps away towards the horn of the uterus: the entire fimbriated margin appeared to us peculiarly and beautifully formed, and arranged to grasp or encircle the ovary, so as to receive the ovule on its being evolved. The laminae represented in the figures* seen passing from the orifices of the duct appeared to us distinctly muscular. The arrangement of the peritoneum is here very peculiar, for it forms a band from what may be considered the horn of the uterus, to the distal pole of the ovary, in the margin of which we find two laminae forming the fimbriated margin. And this is much shorter than the uterine duct, which I found, on careful dissection, to be rather more than seven inches long. The two folds of the fimbriated margin appeared to us to be double, *i. e.* composed of two tunics each; for whilst the external surface has the smoothing proper to the peritoneum, the inner surfaces, or those which come in contact when the laminae close upon themselves, presents, as I have said (when examined under water,) first, the numerous plicae or folds, all running from the direction of the extremity of the uterine duct, whilst the whole surface presents the delicate villous appearance of a mucous membrane.

In the right ovary, fig. 2, when

* It has not been thought necessary to give the figures.

cut in its long axis, I find one large glandular looking body: it formed the projecting mammillary looking point seen in fig. 1. The whole ovary is very vascular. The interior of the glandular looking body shews no appearance of a central cavity. In making the section I divided two cysts, Graafian vesicles, and a small yellow body, about the size of an ordinary pin-head: it appeared to me distinctly glandular.

The left ovarium, upon a section being made, presented very nearly similar appearances, with the exception, perhaps, of less vascularity.

No. 2.—*Uterus precisely as in No. 1.*

Both ovaria appear externally to have large corpora lutea projecting from their surface, and Graafian vesicles are numerous on both ovaria.

Right ovarium, at its most prominent part, presents the appearance of a small rounded opening in the centre of the projecting portion of the glandular body, which indeed resembles strongly the appearance of the partially everted cloaca of a fowl: upon this everted surface there appears not the slightest vestige of peritoneal covering, a vertical incision displays no central cavity.

Left ovarium upon being cut into, but in an opposite direction, presents precisely similar appearances; the yellow glandular looking body is four lines in one diameter, and probably as large as this body ever attains in the sheep.

No. 3.—*Uterus similar to the preceding.*

Right ovary presents two distinct corpora lutea.

Having made the dissection, I proceeded to make four transverse sections of one of these corpora lutea, and although done with the utmost care (under water), I could by no means distinctly make out a central cavity, my bristle appearing rather to have passed between two conglomerate masses. The body extended into the interior of the ovarium to the extent of nearly five lines, and in fact nearly touched the other or superior corpus luteum. Between the two, and consequently in the axis of the poles of the ovary, the interior seemed nearly composed of blood-vessels, still full of blood. I cut through a set of still more minute vessels, which appeared to me to be empty, as if they had

performed their office, and were now contracting previously to disappearing altogether.

The cysts giving the organ so much the tubercular appearance were regular cysts inside the dense fibrous envelope of the stroma of the ovary and its peritoneal tunic. One large one, which I opened with care, was full of a fluid, which, on escape, assumed an opaque membraniform appearance, and I observed three or four white granules, soft, mucous.

I observed that the tunics of the ovary had merely become extremely thin outside, not only the cyst, but the corpora lutea, and I traced a distinct lamina over the projecting yellow body; the transverse sections shewing very perfectly the gradual thinning of the proper ovarian coverings, and that the yellow body penetrated quite to the centre of the ovary; the cysts being immediately outside these yellow bodies.

The left ovary presents externally no corpus luteum, but numerous small yellow points, and many Graafian vesicles on its surface: on being cut into, it proved to be very vascular, vessels carrying red blood; the yellow spots quite visible; and these seem to be inefficient corpora lutea, and quite distinct from the Graafian vesicles: we saw these two textures unquestionably very near each other, but the corpora lutea have no tendency to surround the other.

No. 4.—*Uterus as in the preceding.*

Ovaria have large corpora lutea in each, and the Graafian vesicles are also very numerous. The ovaria are extremely vascular: right corpus luteum when cut into presents appearances in every respect similar to No. 3. This preparation had been a night in water, and the textures in consequence much swollen.

Left corpus luteum, however, being cut in successive slices horizontally, from the most prominent part towards its base, presented on the second slice being removed a rounded cavity, surrounded by a distinct membrane. This cavity appears to have been nearly circular, capable of containing a large pin-head, or about a line in diameter. We observed nothing escape from it when exposed: the interior is perfectly smooth and moist. Its investing membranes send processes outwards into

the yellow body. The cavity is spherical. On returning to the right ovary, and making a similar horizontal section of one half, it was easy to see that the cavity existed in it also, but was not so large. In both cases there is a slight appearance with the surface of the corpus luteum from this cavity.

No. 5.—*Uterus perfectly similar to preceding.*

Left ovary presents a very distinct and prominent corpus luteum, with a projecting part as described in No. 2, and a distinct hole in the centre. A bristle passed into the hole penetrated readily to the extent of four lines. On laying open the canal in which the probe lies, and cavity to which the probe leads, a very delicate membrane is found to invest both, and the texture of the ovary, corresponding to the outer side of the base of the cavity, is exceedingly vascular; *i. e.* numerous vessels, with red blood in them, are cut across.

Right ovary presents externally no appearance of a corpus luteum, but a small depression on the surface, on being minutely examined, shewed a minute orifice, and this being followed was found to lead to a distinct corpus luteum, about half the size of that in the left ovary. A central cavity is also obvious in this one.

No. 6.—*Uterus similar to last.*

Ovary (right) at least twice the size of the left, presenting a very distinct corpus luteum in the usual situation; the peritoneal tunic on the most prominent part is so delicate as not to be distinctly visible, if at all present.

Left ovary presenting only a few Graafian vesicles, but on cutting into the organ we see the commencement of a corpus luteum: it is commencing at the same position of the ovaria as in the specimen of complete development.

On returning to the corpus luteum in the right ovary, although examined and sliced with the greatest care, no orifice on the surface could be detected, and no canal or cavity was found in the centre; a minute white vesicular looking body was observed in making one of those sections nearly about the centre of the corpus luteum.

I may here make a remark which will apply not only to the ovaria just described, but to many others: it often

happens that numerous vesicles, presumed to be Graafian vesicles, are found in the same ovary of different sizes; some very considerable. And this is the case as well in an ovary where there is a corpus luteum, as in one where there is no such appearance, at all events externally. Now, we have never happened to observe that around these vesicles there is the slightest appearance of a yellow body forming, nor any unusual vascularity, either of the membranes composing the vesicle, or of the surrounding ovary.

[To be continued.]

RECORD OF CASES.

By THOMAS MAYO, M.D. F.R.S.

Physician to the Infirmary of St. Marylebone.

[Continued from page 615.]

Erysipelas.

THERE is no disorder in which the principles of treatment have been more broadly and positively stated, and, at the same time, in which less care has been taken to reconcile the differences which they involve, than erysipelas. It is not pretended, in this censure, that remedies of contrary kinds may not be (even simultaneously) efficient towards a given object; since the large incisions of Mr. Lawrence, and the bark of Dr. George Fordyce, may both tend to relieve an oppressed circulation; but it may fairly be alleged, that the cases, or the precise periods of a given case, in which the one or the other of these principles is most appropriate in the treatment of erysipelas, have not been brought out with clearness or precision. Accordingly, a certain

“Metus audax et fiducia pallens”

seems present whenever the practitioner avails himself forcibly, in this disease, of either class of agents. Here, then, according to the views submitted in my first contribution (p. 516), an inquiry is wanted, “which may separate from each other, and individualise in relation to treatment, cases of the same kind.”

The distinctive phenomena of erysipelas may present themselves either in a slight erythematic form, with a partial and well-defined flush upon the face, or other parts of the person, attended with tingling and heat on the affected surface, with general feelings of slight indisposition and depression

of spirits; and these symptoms may depart after a few days with little or no febrile excitement: or they may form the leading phenomenon in a specific fever with cerebral congestion, and generally with extensive swelling of the head and face tending to vesication. Or the erysipelatous state may ensue upon local wounds and injuries, often terminating, under these circumstances, in phlegmonous inflammation.

The second head of the above division, namely, the erysipelatous fever, is that to which I shall endeavour to afford some cases illustrative of treatment, principally in its reference to the above discrepancy.

Sarah Taylor, aged 76, was brought into the Marylebone Infirmary, Dec. 20th, 1842. Her illness commenced the day before, with a rigor, and a sense of heat and weight in the head. The left cheek and forehead were discoloured and slightly swelled, and a throbbing and shooting sensation was experienced; the bowels open; urine copious (at first); tongue not remarkable; pulse small. I prescribed—

Hyd. Chlorid. gr. j.; Pulv. Antimonial. gr. iij. ter. Haust. salin. ammoniat. ter.

22d.—The erysipelas had spread; head more painful and heavy about the temples; pulse low; bowels open; skin hot.

Perstet. Emplast. Lyttæ, temporibus duo.

24th.—Better at all points; much relieved by the blisters.

26th.—A pint of porter.

27th.—Ol. Ricini, ʒij.

Jan. 3d, 1843, 1 A.M.—Left cheek again throbbing, shooting, swelled.

Hyd. Chlorid. gr. iv.; statim. Ol. Ricini. ʒij. vespere.

4th.—Symptoms relieved; pulse depressed.

Quinæ Disulphat. gr. ij. ter.

5th.—Pulse strengthened; general appearance improved. Convalescence was now rapid; no other relapse.

Elizabeth Webb, a maid-servant, aged 32, was admitted into the Infirmary, Dec. 6, 1841. She described herself as having had erysipelas ten days. I saw her on the 7th; she had then been relieved of copious dark-coloured evacuations by the Haust. Rhei cum Magnesia. The face and head were much swelled, and smooth, but pallid. Large purple stains on her person. Tongue quivering, dryish, but little coated. Abdomen not distended. Urine plentiful. She had been delirious in the night; manner approaching to that of delirium tremens. I ordered—

Misturæ Camph. ʒiss., Ammonia Sesquii-
848.—xxxiii.

carbonat. gr. v. 6tis horis. Emplast. Lyttæ parv. epigastrio.

8.—Less delirium last night; tongue as before; bowels open; pulse small; face contracted.

Perstet. in usu haust. c. Tinct. Cinchonæ C. ʒj.

9th.—Delirium increased last night. Face still contracted; great restlessness.

Sumat. porter 1 pint, quotidie. Calomel, gr. ij.; Opii, gr. ss. 8vis. horis.

10th.—A swelling at the occiput had opened, and discharged pus freely.

11th.—Very delirious last night. Frequent yeasty but bilious evacuations; much apparent danger of sinking. No heat of surface.

Sumat. Pil. Calomel, c. Opio, 12mâ. quaque horâ. Olei Ricini, ʒij. cras mane. Emplast. Lyttæ Nuchæ. I allowed an additional pint of porter.

12th.—Blister had acted well. Delirium much relieved; pulse irritable, not weaker; no pain now in the head; no further discharge from occiput; free evacuations.

Perstet. in usu pil. et haust.

13th.—No delirium last night; motions free and bilious; pulse more open, and less feeble. General improvement. The porter was now left off, as sitting heavily.

Perstet. in usu haust. sumat. Pulv. Ipecac. Co. gr. v. bis quotidie.

Convalescence proceeded from this point without relapse, though slowly. The calomel entirely suspended, and sedatives given daily.

Mrs. M——, æt. 78, a lady of a strong frame and constitution, dark complexion, who had undergone much anxiety of mind in bringing up a large family, and had, in the last four or five years, been repeatedly cupped, with temporary benefit, for a sense of weight and oppression in the head, but had received more benefit from mild cordials containing sulphuric æther, was attacked with pyrexia on the night of the 27th of December, 1842. She had complained for some days of indisposition and inappetency of food. She took some aperient pills. These acted freely in the night. The next morning erysipelas appeared on the left side of her face. That evening she vomited freely from 30 drops of Liqueur. Antimon. Potassio Tart. On the 29th, at noon, I saw her. The heat of skin was moderate. The tongue was coated, and white, not dry. The pulse 76, and good. She had been very restless the previous night, and this was the character of all her nights except that of the 29th.

* In the treatment of this case a very excellent general practitioner acted with me.

Every night, to the 3d of January, this lady took Hydrarg. Chlorid. gr. ij., Pulv. Jacobi, gr. iij., Ext. Papav. gr. iss. An aperient senna draught with Sulphat. Magnes. ʒij., was given every second morning. Effervescent salines, containing Ammoniae Sesquicarb. gr. vi.; Potassae Bicarbon. gr. xij. 6tā quāque horā.

On the 3d of January, the erysipelas spreading to the other side of the face, two doses of Hydrarg. Chlorid. gr. iij. were given in the course of the day. Pulse 84.

On the morning of the 4th, the pulse had risen to 96, and was strong, though not hard. The eruption occupied both cheeks, but was desquamating on the left; she was irritable, more, to appearance, from natural temper than illness. An emplastr. lyttæ had been ordered by me the day before, and positively refused by her. This I found on coming to her on the 4th. I then directed five grains of Hydrarg. Chlorid. statim, with a subsequent aperient draught; and I removed the ammonia from the salines.

On the 5th, A.M., I found the skin cool, and the pulse softened. She had passed the preceding day composedly after the calomel, and had slept rather more than usual. The exanthema had made no progress; it was less red; bowels had acted duly.

Perstet. in Haust. Salin. 6tis. Hydrarg. Chlorid. gr. iv. horā somni. Haust. Aperitiv. mane sequenti.

6th.—Pulse soft, but of irritable quickness, occasionally intermitting; manner somewhat hysterical. Skin cool. Tongue brownish and dryish; no pain in the head now, or at any other time. Spirits low. Bowels open. Mouth swelled from the Hydrarg. Chloride.

Disulphat. Quinæ, gr. j.; Ext. Rhei, ij.; bis in die. Mistura Camphoræ, ʒxi.; Ammon. Sesquicarb. gr. vi.; Sp. Æth. Nitrici, ʒss. 6tis. Veal broth.

Up to this time tea and milk, with dry toast, had been her diet; except on the 2d of January, when she had veal broth.

8th, 10 A.M.—I find that in the afternoon of the 7th an erysipelatous blush had appeared over the left leg, and several quinine pills as above had been given. A very restless night. To-day much heat over the leg. Tongue dry. Pulse 98, regular and firm; much tendency to talk about things not before her. Cucurb. cruentæ were applied, ad ʒvj., and were followed by some mitigation of restlessness, and discomfort, which, however, soon increased again, and rose so high, that at 12 nocte Morphia Bimeconat. ʒxv.; Tr. Humuli, ʒj.; Mistura Camph. ʒss. were given, with the effect of giving much sleep. Two draughts of Decoct. Cinchonæ, ʒiss. given in the course of the

afternoon, had had no other effect than that of heating her for the time.

9th, A.M.—Much irritation, collapse, slight subsultus, muttering in sleep, quickened respiration; a good and free evacuation; sufficient high coloured urine. Wine and broth were freely given through this day. Face and leg free from erysipelas, pale.

10th, 10 A.M.—I find that two doses of the bimeconate of morphia have been required during last night to give some freedom from excessive restlessness; and she is breathing short and heavily in uneasy sleep under the sedatives. The pulse had then some strength. Free stimulation was used during the day. At half-past five the pulse was imperceptible; at seven she died.

If this fatal case, in which no autopsy was allowed, be compared with the other successful cases here narrated, relatively to treatment, it may be surmised that the non-application of a blister through the patient's obstinacy was mischievous in the former. This surmise is borne out by the following brief memorandum of another attack of erysipelas, in which I had attended the same lady.

"July 15th, 1841.—Mrs. M—— is just recovering out of erysipelas treated by calomel, aperients, and salines, helped by a blister to the nape of the neck."

Notes thus taken at the time of an occurrence are far more valuable than recollections. I may, however, state, that I remember this attack to have been at the onset similar to the last one, and during its early stage to have run a similar course. In each attack some form of depletory relief seemed desirable; in each the advanced age of the patient rendered abstraction of blood comparatively undesirable; and in that attack in which such abstraction was made, no permanent benefit resulted.

These cases illustrate one point at least in the treatment of erysipelatous fever; namely (what I presume to consider), the valuable effects of blisters, as superseding the erysipelatous action and substituting a mild and safe form of inflammation. In one case, the disease, otherwise similar, had been successfully treated, when this remedy was applied; and took a fatal turn on another occasion when the remedy was omitted. I am well aware that here, as in other forms of disease, this remedy is inapplicable as a substitute for abstraction of blood, where youthful energy or

plethora, or other circumstances of the case, make such abstraction expedient. I wish, indeed, to afford data for a conclusion as to the limits which should circumscribe our use of remedies, in endeavouring to ascertain the extent to which they may be carried.

The following circumstances of a very recent case may afford an additional illustration of the effects of blisters in erysipelas.

Charlotte Stubbs, aged 57 years, is now, February 17th, convalescent under erysipelas. She came into the infirmary February 10th, with pyrexia, sleepiness, and weight in the head; a small quick pulse, a defined erysipelatous blush half way up the calf of the right leg, which was creeping upwards; a tongue dry, and red down the middle. The catamenia had ceased for nine years; she appeared a woman of ordinary health and strength. I saw her first on the 11th; she had then been freely vomited by an emetic of ipecacuanha and potassio tartrate of antimony. There had been rigor, but no delirium. I prescribed a saline of sesquicarbonate of ammonia and bicarbonate of potass, neutralised with tartaric acid, 6tis. and a blister immediately at the upper edge of the erysipelatous blush on the leg.

12th.—Inflammation of leg very great, but no longer spreading upwards. Blistered surface very healthy. Pulse 96; head still heavy, and sleepiness continuing; no erysipelatous appearance there, but a flushed cheek; bowels open.

Hydrarg. Chlorid. gr. iv. h. somni emplastr. lyttæ nuchæ statim.

13th.—Weight of head and sleepiness relieved; pulse soft; leg less hot, but erysipelatous blush more extensive over the foot. Bowels inactive.

Hydrarg. Chlorid. gr. iij.; Pulv. Jalapæ, gr. x. statim.

14th.—Bowels have acted largely during last night. The countenance has become more natural; the tongue cleaner, less dry in the centre. Leg much the same. I ordered another emplastr. lyttæ where the first one had been, the surface being quite healed. The salines had been continued throughout. The urine being irritably passed, and scanty, I allowed two ounces of gin. The diet had hitherto been tea and arrow-root. I now allowed fish.

15th.—Redness and heat of leg and foot remarkably abated. Urine more free. The patient is proceeding most favourably*.

It is perhaps needless to observe, that in this and the other cases, the emplastr. lyttæ have checked the

progress of the inflammation similarly to the described effects of argenti nitras; but, I imagine, with the added advantage of a serous discharge. This subject will be continued.

CASES OF DROPSICAL OVARIA

REMOVED BY THE LARGE ABDOMINAL
SECTION.

By D. HENRY WALNE, Surgeon.

[Continued from p. 690.]

(For the Medical Gazette.)

FOURTH CASE.

IN the month of August last I was requested to visit Miss N—, a lady residing a few miles from Kingston, who was considered to be the subject of ovarian dropsy, attended by rather unusual circumstances; and on the 30th of that month, met one of two intelligent surgeons, the benefit of whose joint advice she generally enjoyed. She had been tapped a few days before, and had also several times previously undergone the same operation, and at one time was relieved of her complaint in a very remarkable degree for several months, under circumstances which led to the belief that a cyst had given way spontaneously, and its contents been taken up by the peritoneal absorbents. The night before I visited her the puncture made by the trocar at the last tapping had opened, and yielded a quantity of fluid, of which full six pints were collected and shewn me. Twenty-five had been drawn off by the operation. Notwithstanding the reduction of her size thus occasioned, the abdomen remained much distended, with distinct fluctuation high up when she was in a sitting or, at most, only a half reclining posture. There was also considerable hardness, chiefly towards the left side, and moveable; and on further investigation I found the true pelvis occupied with a very solid body, the os uteri being situated very forward towards the symphysis pubis. The recent tapping having been performed in the linea alba, and the relief afforded by it being so very incomplete, notwithstanding the bulk of fluid discharged both at and after the operation, I suggested the use of the trocar at another point, above and to the left of the umbilicus, where the fluctuation was very lively, and the

* She has since entirely recovered.—Feb. 27th.

abdomen very prominent; and as the case was complicated, it was agreed that I should renew my visit a few days after this farther proceeding should have been adopted.

In a day or two eighteen pints of fluid were removed by tapping at the spot indicated, and on the 7th of September I again visited her, having the pleasure of meeting both her medical friends. Though more relieved than before, I still found fluid in abundance, and there was much reason to think that ascites was combined with a large encysted dropsy, or that two enormous cysts of the same ovarium existed simultaneously. Some œdema of the lower limbs was apparent at my first visit, but was much less at the period of my second. She had meanwhile taken no active diuretics nor purgatives; the chief object with which we had prescribed being to secure comfortable sleep, and gentle action of the bowels, which were sluggish; the rectum being, I believe, impeded in its natural action by the pressure of the tumor in the pelvis; and having even, when distended, pushed forward the vagina and caused a prolapsus of that part.

Being now much lighter and more equal to the journey, she came to London for the benefit of Dr. Blundell's opinion, she having a very earnest wish to undergo an operation, which I could by no means counsel her doing. Dr. B. and myself, after a carefully renewed inquiry, agreed that her's was not a desirable case for operation, and she was sent back to the country regretting our decision.

On the 3d of October she was again tapped, and by no means before that measure had become imperatively necessary; about fifty pints of fluid being this time withdrawn, from the situation of the earlier tapplings; viz. the linea alba below the umbilicus. She had now heard of my third operation, and its success so increased her desire to undergo the same at any hazard, that she entreated her friends to make the requisite arrangements for again consulting Dr. B. and myself in town, and if we would consent, to place her at once in lodgings in London, that no time might be lost; convinced as she was (not, however, more completely than were the medical men, one and all, who saw the progress of the case), that a few

weeks most probably, a few months with moral certainty, would terminate her existence, were the disease permitted its unrestrained course. The decision of the question rested much with me, and, as I think, properly in part also upon her own intelligent and reasonable judgment in the matter; the more than ordinary danger, and the proportionately diminished probabilities of life, in her case, being placed before her most unreservedly. She was quite decided. An educated, clear-minded, calm-thinking patient of 45 years of age, in the perfect possession of her faculties, and having evidently well weighed the alternatives, is entitled to be listened to when the certainty of a short period of existence in wretchedness on the one hand, and on the other the chance of being cured of a formidable disease with a prolongation of life in a more comfortable state presents itself, even at some, possibly great risk of its immediate loss. "To deny her wish was to condemn her to die, and not only so, but to be a very miserable sufferer till she did die, which must be shortly," was her own mode of expressing the estimate in which she held my reluctance to operate; and the formidable rapidity of her disease in its progress justified her view of the subject. I could take no other myself; and I therefore determined to operate; in which determination her own medical men acquiesced, as did Dr. Blundell, and were all generously willing to take any share of the responsibility that was reasonable. My patient was disposed to take it all upon herself. If she had recovered, I could not have denied that she owed her life to her own calm intelligent, mild determined courage. But, professionally, I am responsible for the decision; and if blame attaches to it, desire that it may be mine alone. Her state when this decision was arrived at requires to be described.

In about a fortnight from the last tapping she had nearly regained the size acquired before its performance. She measured in circumference 49½ inches: from scrob. cord. to pubes 28 inches.

Her general health, with the exception of great feebleness and emaciation, both rapidly increasing, rather good. Tongue clean; appetite good; pulse calm, and of moderate

frequency, soft and very feeble. She had recovered to the greatest degree that could be expected after the tapping, and in a few days more the distress of distension would assuredly destroy appetite and rest, and the partial respite of comparative ease which that operation afforded.

Oct. 19th.—The arrangements being made, much as in my second and third cases, and the skin marked, in stripes crossing the intended line of wound, with a solution of black sealing wax in spirit of wine*, Dr. Blundell, Messrs. Vincent, Law, and Beale, and her medical advisers Messrs. Holberton and Hollier, were placed to the best advantage to counsel and assist in the complicated circumstances which had to be encountered. The patient was seated, and half reclining, her feet firmly planted apart upon the ground, and an ample receptacle placed between them for the fluid that would be discharged. An incision of two inches, in the integuments, &c. in the *linea alba*, below the umbilicus, was made down to the peritoneum, which was then punctured with the scalpel, and an opening made in it large enough to admit a finger. Ascitic fluid flowed abundantly. I now passed a finger into the cavity of the abdomen, to ascertain with certainty the condition of matters, and found an ovarian tumor freely moving in a vast collection of ascitic fluid. As the abdominal parietes became somewhat less tense, the situation of its fundus could be estimated; and before they should become too flaccid, I requested Dr. Blundell to pass a finger into the opening, confirm my judgment as to the state of the ovarian tumor, and stop the flow of fluid till I should have completed the division of the external textures to the required extent for effecting its easy extraction. About fifteen inches of the much attenuated and stretched skin was thus divided. Then the fluid being permitted again to flow was chiefly dis-

charged, and the section of the inner textures completed also, in the manner of my former operations. The tumor came readily forward. The pedicle, formed by the left broad ligament of the uterus, was pierced by an armed needle and tied in halves, and then divided between the ligatures and the tumor. When the latter had been removed, it was my next object to ascertain the character of the hard body which occupied the pelvis. If it had proved a diseased ovary, I should have removed it; as it was found, on drawing it up from its situation, to be an indolent fibrous tumor of the uterus, though of great size, it was permitted to remain, and did not sink again into the pelvis, where, indeed, it had already been productive of serious inconvenience from its bulk, nearly that of a full-grown fetus. The other ovary was found to be healthy. It now only remained to close the wound carefully, which was done with eighteen stitches, lint on each side of it, plaister crossing but not touching the wound, and a bandage; all as in my former cases.

Five gallons of ascitic fluid had been collected, and a tumor removed of 14 lbs. weight, nearly five of which were solid matter, the rest a gelatinous semi-fluid, of various degrees of tenacity, and contained in cysts of various sizes. Here and there, also, a moderate sized cheesy nodule was visible or prominent upon its surface; and at the lower end of the flattened ovate body, an appearance denoting the rupture of a former cyst was very evident. Through the remains of a straight rent the principal cyst protruded, in a rounded form, partly overlapped by the edges of the rent, which edges were separated in turn by the bulging cyst. The patient, having borne the operation well, was placed in bed. Towards its conclusion, a little brandy had been given her, and subsequently an anodyne of Morphine Acetat. gr. $\frac{1}{4}$ in Mist. Camph. \mathfrak{z} ss., which was to be repeated in an hour.

The operation was completed about five o'clock. At six, vomiting occurred. Half a wine-glassful of brandy was given her. Pulse 91 shortly after. The second dose of the anodyne, given at 7 o'clock, was brought up immediately; a third was given at eight, and she did not vomit again till ten o'clock. At this hour the skin was

* This answers the purpose more pleasantly than a solution of Argent. Nitr. since it can be applied a few minutes, or longer, before the operation, as may be most convenient; and it causes no irritation. The marks are very conspicuous.

A French translator of my cases has mistaken the direction of these lines, supposing them to be intended as a guide for the knife in making the incision, and to be made in its course. They cross that line, and shew the correspondence of the divided parts when about to be fixed in apposition by sutures.

warm and moist, and no shivering nor chilliness had occurred. Her mind was clear and cheerful, but she had not slept. Aching pain at the lower part of the abdomen, and in the back, were complained of; but no smarting of the wound, nor any sense of tightness, was felt. Urine, by catheter, \mathfrak{z} ij.: pulse 96: tongue less moist than natural, but no thirst. Has taken nothing but her medicine. She is restless. Temp. 72°.

Extr. Hyosc. gr. v.; Morp. Acetat. gr. ss. statim s. A pint of plain water allowed for the night.

One of her medical friends, Mr. Hollier, accustomed to see her on such occasions, and now present, says she has suffered more after tapping, within the same time. This gentleman was continually in friendly attendance; and after conferring with Dr. Blundell and myself, remained with her all night.

20th, 8 A.M.—Before the pills were procured last night she fell asleep at about 11, and slept a full hour, at the end of which time the pulse had fallen to 86. The pills were given, though she felt she should sleep. After this she dozed chiefly till 1 o'clock, and was then sick; slept comfortably three hours and a half, and on waking observed she felt "so much better." An hour and a half of watchfulness was followed by two hours more sleep. Skin warm, and freely perspiring: tongue moist, but a little brown, as from opiates: some thirst, but has taken only half a pint of water: pulse at present 100, soft, and fuller than before the operation: no shivering nor chilliness: no headache nor confusion of mind has occurred. Her sleep was "very comfortable." Her pain subsided by degrees, and she has now no uneasiness but from the feeling that the bladder requires to be relieved. Is, in fact, "delightfully comfortable," to use her own expression. Urine withdrawn, \mathfrak{z} vij., of high colour. A little air occasionally rises: but she has not vomited since 1 o'clock. Temperature, 71°.

At mid day the symptoms were in most respects so much the same that it is not necessary to record them. She had slept the greater part of the time, and had some uneasiness in the lower part of the abdomen, and in her back. Pulse 107. No tenderness of the abdomen. Urine drawn off, \mathfrak{z} ij.: this afterwards done at proper intervals.

5 P.M.—As before. Occasional eructation of air and a little bitter-tasting fluid.

10 P.M.—Has just vomited near half a pint of green acid fluid, and still feels sick, as she has done in the evening. She is also teased with flatus and occasional griping: rectum-tube used to no purpose. Pulse 112: skin warm and perspiring: no headache, shivering, chilliness, nor hiccup. Soda-water, with a little brandy, given.

R Morp. Acet. gr. ss.; Extr. Hyosc. gr. ij. in pil. stat. s. Sumat. etiam Mist. Camph. \mathfrak{z} ss.

21st, 8 A.M.—Passed a tranquil night, with more than four hours of sound sleep, and repeated dozings. Vomiting has not returned: flatus moves noisily in the intestines: skin very warm, and rather profusely perspiring; and a little roughness, like a papular eruption, is felt on some parts of the chest. Pulse 113, soft and feeble. No headache: mind clear and cheerful. Enjoys the soda-water, and once had two tea-spoonfuls of brandy with it. Tongue almost clean and not dry. Urine spontaneously voided, \mathfrak{z} vij. at 8 o'clock without difficulty or sensible effort. The œdema of the legs is much reduced. She has no tenderness of the abdomen, nor pain in the back. Feels a little disposed to bilious eructation. To have a tea-cupful of beef-tea with salt in it. Temperature, 71°.

2 P.M.—She was sound asleep when I called. Beef-tea and soda-water had been taken, and no sickness had occurred. \mathfrak{z} vj. of urine had been voided. I postponed seeing her, on receiving this report, till 5 P.M. and then found that she had slept several hours very soundly. The flatulency had scarcely troubled her since she took the beef-tea. It is now 48 hours from the time of the operation, and she has in all taken not more than a quart of water, two bottles of soda-water, and about \mathfrak{z} vj. of beef-tea. Pulse 105, firmer: skin temperate and moist. She is less warmly covered, and has perspired less. Tongue moist, and, for the most part, clean: urine passed, \mathfrak{z} vj. Has slight headache, perhaps from being suddenly awakened. Nothing else to complain of.

10 P.M.—Visited by Dr. Blundell as well as myself. Pulse 102, full, and moderately firm. Has had another cup of beef-tea, and soda-water occasionally. No fresh symptom to note.

R. Extr. Hyoseyam. gr. v. ; Morphiae Acetat. gr. ss. in pil. ij. h. s. s.

22d, 9 A.M.—Had repeated intervals of sleep in the night, but was disturbed by irritation of the skin. Took beef-tea and soda-water, and this morning some tea and a sopped Norwich biseuit : the first solid food yet taken. Complains of heat and a papular eruption. The day very close. Temperature 74°. Pulse 97, full and soft. No discomfort of bowels, nor any movement of them. The bed-clothes to be lightened, her linen changed, and the temperature of the room gradually lowered.

5 P.M.—The changing of linen, &c. fatigued her, but she is now very comfortable. A jelly was given, and some beef-tea. Pulse 93, full, and firmer than before; Mr. Hollier says, "better than it has been for five months." Urine 3vij. When we remarked on its scantiness, she observed that so much in a whole day was more than usual with her of late. Tongue clean and moist. Nothing to complain of.

10 P.M.—As before. Pulse 95.

Rep. Pilul.

23d, 9 A.M.—Pulse 92. Had a good night. No change to note. Takes beef-tea, calves'-foot jelly, and biscuit, all in moderation.

2 P.M.—Wound dressed (93 hours from the operation): all the stitches removed: it appears to be substantially united: a few little irregularities of the edges, from the puckering of the redundant but shrinking skin. Lint laid along it, and plaister over this from side to side of the abdomen.

10 P.M.—Several of her friends have visited her to-day, including Mr. Holberton, her other medical friend from the country, who is much pleased with her state. She complains of smarting in the wound, and has been teased with flatus. Pulse 102. No movement of the bowels hitherto. An enema given of two pints of warm water: it brought away a copious motion, which afforded great relief.

Rep. Pilul.

24th, 9½ A.M.—She remained comfortable last night after my visit, and slept several hours. At 5 A.M. took some beef tea, and then slept till 9, when she took her breakfast of tea and toast. Says she is now comfortable, and free from smarting or other uneasiness. Pulse 100 just after breakfast.

5 P.M.—Pulse 95. Has taken beef tea and jelly. Has been rather teased with flatulency. When she turns in bed the wound smart. Its lower end yields a little thick healthy pus. Tongue drier to-day, and a little furred.

10 P.M.—Dr. Blundell met me. Pulse 90, fuller again, and firmer. The colon is much distended with flatus. No motion. Tongue cleaner, and more moist. Does not complain of anything material.

Enema Aquae tepid.

25th, 9 A.M.—Had three motions from the enema, with much faeculent matter, as well as abundance of flatus. Her night was rather disturbed, and flatulence still inconveniences her. Pulse 88. Skin moist and warm. Has taken an egg and toast, with tea, for breakfast.

R. Spir. Ammon. Ar. 5ss. ; Mist. Camph. 3iiss. ; M. ft. haust. pro re nata sumend.

5 P.M.—Pulse 92. In other respects as before.

10 P.M.—Seen by Dr. Blundell also. Has been troubled with flatulency throughout the day, and does not seem quite so well as yesterday. Pulse rather more frequent: skin warm and moist: no motion: urine not deficient: has taken chicken, and some beef-tea, and soda-water with a little brandy added, once or twice. Tongue drier, and somewhat furred. Wound dressed. Healthy pus is furnished along that part which is not already healed, and there is a blush of the skin at its edges. Lint laid along it, supporting-plaisters across the abdomen lightly applied. The healing power seems deficient, which, recollecting her extreme feebleness before the operation, is not to be wondered at.

R. Decoct. Cinchon. 3ij. ; Spir. Ammon. Ar. 5ss. ; M. ft. haust. ter quotidie sumend.

R. Extr. Hyoseyam. gr. xj. ; Aloes Barb. gr. ij. ; Ol. Carui, gt. ij. ; M. ft. Pil. ij. ; h. s. sumend.

26th, 1 P.M.—Passed an indifferent night, being annoyed with flatulency and distension of the intestines. Has had three motions, one copious and faeculent, two liquid, with much flatus. Pulse 90. The rectum-tube used with little effect. No sickness. Is thirsty. Tongue dry and brownish. Thinks the dressings too tight, which they may be from distension that has taken place

since they were applied. I loosened the ends of the plaister on one side, and Mr. Hollier did so on the other after I had left her.

10 P.M.—Is rather better. Tongue furred, and white at the back; moist and clean towards the tip; it is much less dry on the whole, and her thirst is less. Urine not deficient, but of higher colour. Pulse 96, and soft.

R Extr. Hyoscyam. gr. v. in pil. ij. h. s. s.

27th, 2 P.M.—Had a good night. Tongue cleaner. Is less flatulent. Has taken nourishment less frequently, and feels the better for the change; but enjoyed her breakfast of an egg, toast, and tea, and had a mutton chop, with a little brandy and water, for dinner. Pulse 98, full and firm. No sickness, headache, nor pain of any kind, except a little occasional griping before the bowels move. Is in better spirits. Wound dressed. Healthy suppuration along it. It is more closed at a point where, from the puncture made in the last tapping, the skin was less healthy, and did not unite at first so well as elsewhere. The upper part, however, where it was dry and apparently soundly healed some days ago, now furnishes matter, and the thread-holes have opened afresh in several places with an unhealthy pustule at each. The skin of the abdomen, at a distance from the wound, has also festered under the plaisters. The blush in the line of wound has much disappeared. Dry lint laid along it, and other dressings as before.

10 P.M.—Has been more comfortable all day, except from 4 to 5 o'clock, after turning on her right side rather hastily. She then was in pain, but became easier when again lying on her back. Has slept this evening. Bowels again moved. Pulse 98, having just taken some beef-teen. The Decoct. Cinchon. &c. seem to agree, and have been taken regularly. Tongue improved. Urine 3xij. since the morning, besides what passed at the time the bowels were relieved.

Rep. Pil. c Hyoscyam.

After I left her she was so very comfortable that she wished her kind friends, Mr. and Mrs. Hollier, both to go to bed, which hitherto they had never done at the same time, one of them being always in close attendance upon her. A careful and at-

tached servant remained in charge of her, and at about 5 in the morning, thinking her mistress not so well, called Mr. H. to see her. He found her very uneasy, suffering from flatulent distension, and pain in the upper part of the abdomen on the right side. She had been sick, and her pulse was from 114 to 120. Mr. H. gave her some soda-water with a little brandy in it, and then an anodyne. He saw her again, and found her pulse much more frequent, at 8 o'clock of the

28th.—I was fetched to her immediately. Most alarming symptoms had come on. The pulse much exceeded 140, and was small as a thread, and so feeble as to be scarcely felt with sufficient distinctness to be numbered accurately. She vomited constantly. Her feet and hands had lost their natural warmth, though the room was of good temperature. They had begun to acquire lividity. A perspiration of a clammy character covered the skin, and she moaned with distress, complaining of uneasiness in the right side and across the abdomen, and of great distension. Her mind was still calm. Anodynes were administered; hot applications to the extremities and stimulants used. It was quite evident that she had but few hours to live. She struggled through the day beyond expectation, and died at 8 in the evening.

On the following evening, Dr. Blundell, Messrs. Hollier, Beale, Law, and myself, examined the abdomen. The external appearance of the wound evinced in a remarkable manner the deficiency of reparative power with which we had been contending. Many of the points of skin where the suture-threads had penetrated were open, as if they had been recent punctures in a piece of softened parchment. At that part where the operation of tapping had been last performed, and where the skin, at the time I made my incision, was still slightly red, and a little elevated, there was an opening of the size of a large quill. A quantity, perhaps half a gallon, of serous fluid had escaped at this opening on the body being moved before we arrived, and there was now a ready communication between the air and the peritoneal cavity. The part had probably been but slightly agglutinated, or the connection previously established had been again nearly dissolved by suppurative

process within the last few days, at the time when the other parts of the wound seemed to retrograde. Where the ligatures hung forth, the lips of the wound were also apart, but this was less remarkable, their presence being considered. Here, however, they were not so surrounded with adhesive deposit or sprouting granulations as is usual at such a period when the healing powers are undiminished.

An incision was now made two inches to the left of, and parallel to the wound, but longer at each end; then transverse sections towards the right side from both ends of the first cut, and a long flap of the parietes of the abdomen turned back, so as to exhibit without disturbing the interior of the peritoneum, where it had been divided in the operation. Nothing could exceed the beautiful perfection of the internal repair which had been effected throughout a very large portion of the entire wound. From its extreme upper point down to the quill-sized opening above described, the peritoneum was so completely and smoothly united, cut edge to cut edge, without a single attachment to any subjacent viscus or any apparent diminution of its natural smoothness and moist polish, that at first it required close inspection, and a comparison of situation with that of the wound in the external parts, to give us assurance of the exact position the division had occupied. Below the quill-sized opening, near which some long and firm adhesions to the intestines had been formed, we again observed the same complete union of the lately divided peritoneum, extending downwards till it reached a part where the peritoneum and other textures of the abdominal parietes had lain upon the rounded surface of the indolent uterine tumor described in the operation. There a different state of things was observable. For nearly three inches just where, whether the minor or the major operation be performed the peritoneum is equally divided, its wounded edges in two regularly curved lines, half an inch at least asunder at their greatest distance, had been mechanically kept from uniting by the presence of the tumor which nestled between them. Here attempts at adhesion had been in vain made. Suppuration had been substituted. The fore-part of the tumor itself was injected; matter and much lymph lay upon its surface; its

right side most red from recent inflammation; its left exhibiting more pus, lying beside the ligatures, and a collection of some spoonfuls accumulated near the tied broad ligament, enclosed, however, by adhesive deposit which preserved it from diffusion within the peritoneum. This membrane itself, chiefly on the right and very partially, had also been the seat of recent inflammation; some thin films of plastic deposit lay upon its surface, and towards the right hypochondrium, as broad as the palm of a man's hand, it was reddened by injected vessels. At the middle and left side of the abdomen scarcely any trace of the kind was observable. A small quantity of a reddish serum, quite clear, was found in its cavity, doubtless of the same character as that which had escaped before we opened it.

The viscera generally were healthy; the intestines distended with air and of a dark marbled greyish purple hue, except where the redness was observable. The uterus was elongated and flabby, its back and fundus occupied by the large fibrous tumor of the ordinary character of that structure, and the front wall by a smaller tumor of the same description, about the size of a French walnut.

The attention of my readers will, I hope, be arrested by a few of the particulars of this case and post-mortem examination, but I may be permitted briefly to direct it to some of the circumstances which are of most interest, lest they should engage it less than from their practical value is desirable.

First. How important is the reparative power to the safety of the patient in peritoneal wounds, and how necessary, therefore, that operations for ovarian disease should be performed before the constitution has been exhausted by repeated tapplings, which, becoming more and more frequently necessary as we continue to resort to them, drain the system of its vigour with increasing rapidity. The surprising amount of ascitic fluid, five gallons, formed in less than three weeks between the last tapping and the day of operation, must have diverted nearly all nutrition from its proper course. When the fluid forms rapidly within a cyst the observation equally applies. Feeble, however, and little sustained as was the healing process, there can be little doubt that the patient would have recovered but for the presence of the

hard tumor, and its interference with the closure of the recently wounded parts; and I believe that could the operation have been performed some months sooner she would have recovered in spite of that disadvantageous circumstance.

Secondly. How perfect is the restoration of the free covering of the viscera, the parietal peritoneum, even when the power of repair is feeble, provided the adjustment of the wound be carefully completed, and remain undisturbed. How important, therefore, are the practical measures directed to this end; measures which are passed by as 'simple' by the great majority of those who do not hesitate to put forward their opinions as to the advisability of such operations, whilst they are content at the same time to be ignorant of what may make them safe and proper.

Thirdly. The upper portion of the wound would seem not to have been at all a source of danger in the case: shewing with what propriety the attenuated abdominal parietes may be extensively divided to effect the easy removal of diseased ovaria when any doubt exists as to the very simple, unadherent character of the disease. In this instance the tumor might as well have been almost entirely solid for any facility which reducing its size could afford. The largest cyst may have contained a quart of fluid, or even a little more, but the other cysts were small, very numerous, and having thick walls must have been withdrawn through a considerable opening.

In conclusion I may observe, that so far from seeing in the foregoing history any circumstance calculated to discourage me in the performance of operations for the removal of diseased ovaria, I draw from its consideration additional assurance of their safety and of their value; safety when timely performed, value in preventing the occurrence of such complicated accumulation of misery, and in preserving lives which the diseases they combat would otherwise destroy. I trust many practitioners will, upon the perusal of the narrative, readily acquiesce in my own estimate of the matter, when I conscientiously declare that nothing has yet occurred in my practice to shake my confidence in such resources of our art.

Guilford Street, Russell Square,
London, January 14, 1844.

CONTRIBUTIONS TO PATHOLOGY.

By JOHN PERCY, M.D. Edin.

Physician to Queen's Hospital, and Professor of Organic Chemistry, Queen's College, Birmingham.

(For the London Medical Gazette.)

Bright's Disease, with Analysis of the Urine.—Examination of the Blood and Brain for the presence of Urea.—Note on the Constitution of Nitrate of Urea.

MARCH 24th, 1843.—John Kirwan, admitted in-patient of the Queen's Hospital, æt. 47. Of robust frame. Coach-smith. Of very intemperate habits, having for many years drunk freely of spirits. Three years ago, was confined to his bed with rheumatism during three weeks. Has since been liable to attacks of pain in the chest, accompanied with dyspnoea and palpitation. Six weeks ago, he first observed swelling of his feet and ankles. His body is now generally anasarcaous; his face and eyelids especially are swelled and puffy in the morning. Distension and fluctuation of abdomen. Penis and scrotum much distended with liquid. Distinct bruit accompanies the first sound of the heart; loudest over the sternum below the second rib; indistinct, and occasionally absent, at the apex; heard, also, in the course of the carotids. No pulsation of external jugulars. Percussion natural. Sonorous râles in anterior part of chest. Appetite good. Tongue flabby, coated yellow in the centre. Bowels reported regular. Pulse 100, compressible. During the last six weeks, he has been obliged to rise two or three times in the night to pass urine. There is a hard, defined, pulsating tumor, of the size of an orange, in the right popliteal space. Loud bruit is heard on applying the stethoscope to this tumor, which was first perceived six years ago, the patient, at that time, having been struck with a piece of iron on the right popliteal space whilst engaged in tiring a wheel. He has suffered no inconvenience from it. Before admission, he has taken mercury, as is evident from the color of his breath.

The patient continued under my care in the hospital until his death, which occurred in September. The urine contained albumen. An examination of this excretion is subjoined. Hydragogue cathartics, such as elaterium, jalap, and gamboge, were prescribed with temporary benefit. The diuretic treatment was also tried, and with the same result. During the progress of his illness, symptoms of congestive apoplexy supervened, and required active treatment by cupping and vene-

section. I shall introduce only occasional extracts from my journal.

April 1st.—Bowels have been freely moved; watery stools. Anasarca generally diminished. Pills (Elatarium, gr. $\frac{1}{8}$ in each pill, with Hyoscyamus) occasioned sickness and vomiting. Pulse 100, regular, of moderate strength. Tongue indented by the teeth, on each side coated, clean along a stripe in the centre, and at the edges. Frontal headache. Last night rose twice to pass urine, and four times in the previous night.

May 13th.—Anasarca much increased. Took two elatarium pills yesterday, which produced three watery stools. Great tendency to drowsiness.

Cuc. Cr. Nucha.

15th.—Considerably relieved by the cupping. Passed urine twice last night.

20th.—Yesterday had Cambogia gr. iij. c. Potassæ Bitart. \mathfrak{z} j. An hour afterwards had a copious watery motion. Bowels have been moved four times since. The gamboge-powder did not induce sickness. Cupping at the nape of the neck to \mathfrak{z} iv. was repeated yesterday, and was followed by great relief of the head symptoms. Distension and fluctuation of abdomen. Passed urine three times last night. Tongue moist, pale, and smooth.

24th.—Symptoms as before. Head continues relieved. Much complaint of pain across the loins, but there is no tenderness on pressure in this situation. Leucophlegmatic countenance. Distinct bruit with the first found of heart.

27th.—Abdomen extremely distended, and tense. A diuretic mixture, containing Tr. Digitalis, Sp. \mathfrak{A} th. Nitrici, and Acet. Potassæ, was prescribed. A solution of Bitartrate of Potass and Biborate of Soda for common drink.

11 p.m.—Orthopnea. Violent sickness, and pain in right iliac region.

V. S. ad \mathfrak{z} vj. Effervescing mixture containing Carbonate of Ammonia, Tartaric Acid, and Liqueur Opii Sedat.

28th.—Slept well. Feels better. Abdomen not so tense or painful.

June 8th.—A discharge from the right ear. In other respects as before.

14th.—Cough, with muco-purulent expectoration. Sonorous râle. Dyspnea last night. Inflammation of conjunctiva of right eye.

21st.—Face extremely œdematous. Occasional dyspnea. Restless night. No vertigo. No return of nausea. Pain referred to lower part of abdomen. No complaint of pain across the loins.

July 1st.—June 28th, \mathfrak{z} vj. of blood taken by cupping at the nape. Relief. Occasional dyspnea. Sleeps much. Anasarca

to a great extent. Passes urine three or four times daily.

16th.—Much worse of late. This morning, wandering delirium. Thinks he has been hung. Red blush in several places on the lower extremities. Scrotum and penis much distended with liquid. Pulse regular, firm.

19th.—I saw him last night. He complained of being tormented with spectres, some of which had no heads. Discharge from both legs in several places. Bruit with the first sound still distinct. Occasionally he appears to be much exhausted. Has taken constantly an æthereal mixture which was prescribed before.

Aug. 30th.—During the last several weeks he has continued considerably improved. The places from which liquid had escaped were progressing towards healing. Liquid, however, is now discharged from them. Ascites continues. Anasarca greatly diminished. Cough, with expectoration; "cannot get up his phlegm." Lies most easily on the right side. Aspect of countenance leuco-phlegmatic, having a yellowish-white tinge, expressive of anæmia.

Sept. 9th.—The sores from which the serous liquid has been long draining are now almost entirely healed, with the exception of one or two spots on the inner part of the right thigh. Œdema of face considerably increased.

He died comatose Sept. 15th.

Autopsy.—*Head*:—Brain somewhat softened.

Chest:—Clear dark-coloured serous liquid in both pleural cavities, largest quantity in the right. No adhesions. No evidence of disease in either lung. *Heart*:—Nearly four ounces of clear yellow liquid in the pericardium. Recent and slender adhesions. Weight of heart, with the vessels, 1 lb. 1 oz. (avoidupois). No coagula. Aorta dilated at its origin. Internal surface rough. All the valves without deposit, normal.

Abdomen:—Peritoneal cavity contained about eight quarts of clear liquid. Shreds of lymph about the umbilicus. *Stomach*:—Small and contracted; coats very thick. *Small intestines* contracted. *Liver*:—Weight, $4\frac{1}{2}$ lbs. (avoid.) Peritoneal surface opaque, and thickened in places. *Kidneys*:—Weight of right 5 oz. (avoid.); of left, $4\frac{1}{2}$. Distinct appearance of granular degeneration on the surface, deprived of fibrous coat, and internally.

The tumor in the popliteal space was found, as expected, to be a true aneurism, of the size of a small orange.

Examination of the urine.

March 25th.—Urine passed this morning; very pale; not clear, even after standing; mucous cloud; filters bright; reddens litmus; frothy by agitation; sp. gr. 1016°; temp.

61° Fah.; abundantly coagulated by heat and nitric acid. I boiled some of the urine for several minutes; filtered perfectly bright; no further coagulation by addition of nitric acid to filtered liquid. I proceeded to make an analysis; but, unfortunately, an accident occurred in the determination of the urea, which, however, only existed in small quantity. 1,000 grains contained, of—

Water	964.92
Albumen	9.78
Fixed saline matter	8.80

The whole amount of solid matter being 35.08, we have, by deducting from this quantity the sum of the albumen and fixed saline matter (18.58), 16.50 of urea and indeterminate organic matter. The evaporation was effected, first over the ordinary steam bath, and then in Berzelius' apparatus. The fixed saline matter contained alkaline carbonate, the aqueous solution restoring the colour of reddened litmus. I found also earthy phosphate, alkaline chloride, and sulphate; but I did not search for alkaline phosphate.

May 16th.—Urine passed yesterday; pale brown; sp. gr. 1020°; turbid, and slightly so after filtration; abundant coagulation by heat, and also by nitric acid; filters perfectly bright after boiling; no turbidity produced by nitric acid in the filtered liquid; strongly acid; I was not able to detect globules by the aid of the microscope. In this analysis I operated, as usual, upon three portions, of 500.0 grains each. The drying was effected in Berzelius' apparatus, at 212° Fah. 500 grains left 26.59 of dry residuum. The albumen was determined by washing the dry residuum, first with alcohol of 0.834, and then with distilled water, until the solution ceased to be affected by nitrate of silver. By the ordinary process I obtained 7.86 grains of nitrate of urea, which (estimating the salt as $(C_2N, O + NH_3 + HO) + NO_3 + HO = 123.912$) corresponds to 3.84 of pure urea.

Analysis of 1,000 grains.

Water	946.82
Albumen*	22.64
Urea	7.68
Uric† acid and indeterminate organic matter	17.52
Fixed salts soluble in water	5.20
Chlorine, sulphuric, phosphoric, and carbonic acids	
Potass and soda	
Earthy phosphate	
		1000.00

On the addition of distilled water to the

* Ash deducted.

† Small crystals of uric acid were separated by addition of acetic acid.

incinerated residuum, in numerous spots where the little masses of ash were detached by the water, the platinum had a blue colour. The solution was strongly alkaline, immediately restoring the colour of reddened litmus. Phosphoric acid was abundant; and copious precipitation was occasioned by the addition of bichloride of platinum. The proportion of earthy phosphate, it will be observed, was small.

Sept. 15th.—Urine last passed. Colour pale brown; sp. gr. 1015°; temp. 70° Fah.; turbid, and continues so after filtration; extremely offensive and ammoniacal; an abundance of minute prismatic crystals of ammoniaco-magnesian phosphate; flocculi separated by heat, insoluble by the aid of nitric acid. A portion was evaporated and incinerated, and the incineration was aided by nitrate of ammonia. The aqueous solution of the residuum instantly restored the coloured of reddened litmus. Only a trace of chlorine was detected by the addition of nitrate of silver and nitric acid.

Tables of the specific gravity of the urine.

In the second table is indicated the specific gravity of the urine passed during the night.

Examination of the blood, with a view to the detection of urea.

May 19th.—I took 400.0 grains of the

serum of Kirwan's blood, obtained by emptying at the nape this morning. I evaporated to dryness over the steam bath; the residuum was twice treated with distilled water at a gentle heat; the aqueous solution was decanted, and evaporated to dryness; the residuum was twice treated with alcohol, sp. gr. 0·834; the alcoholic solution was filtered, and evaporated to dryness; to what remained was added a small quantity of water, and then nitric acid.

22d.—I observed a minute quantity of precipitate, in which, however, I could not, by the aid of the microscope, detect any crystals of definite form; the result must, therefore, be considered negative.

Examination of the brain, with a view to the detection of urea.

Jan. 20th, 1844.—Having left a portion of Kirwan's brain, well broken up, in alcohol since the period of his death to the present time, I proceeded to search for urea. Filtered alcoholic solution; filtered liquid became slightly turbid. I evaporated first in the chloride of calcium bath, and then, at a gentle temperature, on the sand bath. Oily matter separated as the evaporation proceeded. Added water to the residuum; filtered; evaporated filtered solution; and, to residuum added nitric acid of sp. gr. 1·2 in excess.

24th.—No trace of crystallization of nitrate of urea. In this case, also, the result is negative.

Note on the constitution of nitrate of urea.

I may here appropriately append a note on the constitution of nitrate of urea. It will be observed that I have estimated the salt as containing an equivalent of water, according to Regnault's experiment, which I am persuaded is correct; and in proof of which I introduce an analysis of my own.

I took 34·04 grains of pure nitrate of urea, reduced to fine powder, and dried during several days consecutively in Berzelius' apparatus at 212°, but without desiccation of the air by chloride of calcium. I dissolved the nitrate in distilled water, and cautiously added pure carbonate of baryta in excess. The nitrate of baryta was decomposed by an excess of sulphuric acid, and the weight of sulphate of baryta was accurately determined. From this I could deduce the weight of nitric acid existing in combination with the urea, and could consequently deduce also the weight of urea. I obtained 31·974 of Ba, SO₃. Admitting urea to be C₂N₂O + NH₃ + HO, C=6·125, N=14·186, O=8·013, H=1, Ba=76·676, and SO₃=49·159 (on the authority of Berzelius, vide *Traité de Chimie*, t. 3ième), we have

Ba, SO ₃	=	31·974
Ba	=	20·983
NO ₂	=	14·846
Urea	=	16·596
Water	=	2·598
For, 34·04 — (14·846 + 16·596) =		2·598
Per cent		
Urea		48·754
Nitric acid . .		43·613
Water		7·632

99·999

Regnault's analysis (Becquerel, *Semiotique des Urines*, p. 33—)

Urea	48·938
Nitric acid . .	43·781
Water	7·281

100·000

Calculated	
Urea	48·945
Nitric acid . .	43·781
Water	7·273

99·999

It is evident that the nitrate of urea which I employed was not perfectly deprived of hygroscopic water; for the excess of water, as shown by the calculated analysis, amounts to 0·359 per cent.

OBSERVATIONS.—The case which is here detailed does not present any remarkable feature of interest, affording only an ordinary illustration of the course of Bright's disease, or granular degeneration of the kidneys. The predisposing cause may be clearly traced to the excessive use of ardent spirits, as it appears to be well ascertained that habitual intemperance is frequently followed by the disease in question. The evacuation of serous liquid by spontaneous openings in the skin in several parts of the body was attended by obvious temporary relief. I expected that diffuse cellular inflammation would be the consequence, and was surprised to observe that these openings, notwithstanding the constant drain from them during a considerable period, were at length nearly all healed. We should be cautious in inferring from a case of this kind the propriety of removing the anasarca by artificial scarification, as fatal effects have been speedily induced by such practice, death being occasioned by exhaustion consequent on diffuse cellular inflammation. I have myself witnessed fatal cases of this kind. It has been sug-

gested, if I mistake not, by Dr. Budd of King's College, that the urea existing in the serous liquid may, probably, by virtue of its irritant property, be the exciting cause of this inflammation in the case of evacuation from openings on the surface. This suggestion, however plausible, requires to be verified. In the case of Kirwan, urea was, comparatively speaking, excreted in considerable quantity in the urine; and I was unable to detect this substance in the blood, when the symptoms suggested the probability of the brain being injuriously affected by its presence in increased proportion. It has, however, as is well known, been frequently separated from the blood in Bright's disease in very sensible quantity. From the bruit, which accompanied the first sound of the heart, I suspected the existence of disease of the semilunar valves of the aorta; but this suspicion was not confirmed by the autopsy, which revealed only as the cause the roughened condition of the internal surface of the arch of the aorta. Of the popliteal aneurism the patient made no complaint, and it was some time after his admission before the tumor was discovered. It is singular that it existed for so long a time without appreciably increasing. In respect to treatment in the confirmed stage of this disease it is obvious that the only indication is the diminution or removal of the anasarca either by the kidneys or from the cutaneous or intestinal surface. In the case before us, hydragogue cathartics appeared to afford the most relief. However, from any plan of treatment we can only anticipate temporary benefit. Local depletion, as cupping at the nape, is urgently required when there is threatening of coma. In proof of this, I may confidently appeal to the history of the case before us.

The urine presented the characters common to that excretion in Bright's disease. The average specific gravity deduced from the second table was only moderately low, being 1016.6. The extremes, so far as our observations extended, were 1037 and 1003. I did not accurately ascertain the average quantity of urine passed; although I am satisfied that generally it was not in that respect below the standard of health. The urea was not evacuated in the natural proportion. In the

analysis given it amounted only to 7.68 parts in the thousand; whereas, in health, it at least amounts to double that quantity. The proportion of earthy phosphate was much less than in healthy urine, in which it exists generally in the proportion of 1 to 1000. In the last urine passed, only a trace of chlorine, in combination with a fixed base, was detected. Whether it existed in larger quantity in the urine before evaporation and incineration, I did not ascertain.

[To be continued.]

CASE OF POISONING BY THE BICHROMATE OF POTASH.

To the Editor of the Medical Gazette.

SIR,

I BEG to hand you the following report of a case of poisoning by the *Bichromas potassæ*, for insertion in your journal. The toxicological works of Christison and Beck, and the admirable manual just published by Mr. A. S. Taylor, contain very short notices of the poison in question; and but one case where there was a post-mortem examination of the body.—I am, sir,

Your obedient servant,

GEORGE WILSON, M.R.C.S.E.

Surgeon to the House of Recovery, &c.

3, St. Peter's Square, Leeds,
Feb. 19, 1844.

William Rothery, ætat. 64, from reverse of circumstances had been for some years the subject of melancholy, and had once attempted to commit suicide by hanging.

On the 13th December, 1843, he walked from Huddersfield to Leeds, bringing a sum of money to his son-in-law, who resides at the latter place; but was unfortunate enough to lose, or be robbed of, the money on his way. He went to his son-in-law's house, seemed dejected at his loss, and, after having drunk about a pint of home-brewed beer (of which the former also drank several times), retired to bed at about 11 o'clock p.m. A grandson, who slept in the same bed with him, said that he snored very hard, and on the following morning he was heard by several members of the family to be breathing loudly as they passed his room door; but as he usually did breathe so when asleep, and they sup-

posed he might feel fatigued by his walk of the preceding day, they were not at all alarmed or suspicious, and did not disturb him: this was about 9 or 10 o'clock A.M. At about 11 o'clock in the forenoon, however, his daughter went to call him up, and found him dead. I was sent for immediately, and arrived within ten minutes.

He was lying upon his left side, in an apparently easy posture, the lower extremities a little drawn up to his body; his left hand under his face. His countenance was pale, placid, and composed; eyes and mouth closed; pupils dilated; no discharge from any of the outlets of the body; no marks or remains of vomiting or diarrhoea, nor any stain upon his hands or person, or upon the bed-linen or furniture. The surface was moderately warm.

On searching the deceased's clothes, I found only a few halfpence, and a paper containing about lb. ss. of black powder; which, it appears, was a sample of a new dye-stuff, which he had brought for the inspection of some dyers at Leeds.

By order of the coroner I inspected the body the same evening, in the presence of another surgeon.

The subject was remarkably tall, muscular, and well-formed. The skin was clear, and free from all mark, eruption, or wound. The limbs were rigid, but had not quite lost their warmth.

On removing the calvarium, the brain and its membranes appeared perfectly healthy and natural; neither congestion nor effusion existed on any of its surfaces, nor in the substance of the organ itself.

The thoracic viscera were equally healthy; no interpleural adhesions. The structure of the lungs natural; no engorgement nor abnormal deposit. The heart was moderate in size; there was no particular distension of its pulmonary side, nor of the vessels connected therewith. The pericardium contained about four drachms of clear serum; the pleuræ about an ounce and a half each.

On opening the abdomen, the viscera generally were loaded with fat; but in other respects presented no unusual appearance externally. The liver contained several hydatids, the largest being the size of a hen's egg; in other respects its structure was healthy. The gall-bladder was shrunk, and nearly empty.

The structure of the kidneys was quite natural, with the exception of an hydatid on the surface of one of them. The bladder contained about O.s. of urine.

The stomach was removed in the usual manner, ligatures having been first applied to the lower part of the œsophagus and commencement of the duodenum. On opening the stomach, nearly a pint of black, turbid, inky-looking fluid was discovered; this was set aside. The mucous membrane of the stomach was red and very vascular, particularly at the union of its cardiac extremity with the œsophagus, but this redness I considered at the time might be partly accounted for by the intemperate habits of the deceased; who, I was informed, had lived almost entirely upon malt liquor. The redness did not extend into the œsophagus or duodenum, nor were there any dark stains observable upon the mucous surfaces of these, or any other part of the intestinal canal.

In the absence of any obvious cause of death, I suspected that the deceased had died from poison, and the similarity, or rather identity, of colour of the contents of the stomach with that of the dye ware found in his clothes, pointed to the latter as the substance in which the poison was most probably contained: accordingly, on analyzing them, I found they were in fact the same, and that both contained a considerable proportion of bichromate of potash. Besides this, the bulk of the dye-powder was composed of bitartrate of potash, (argol) and fine sand.

The history and post-mortem appearances of this case would seem to indicate that the salts of chromic acid do not act upon the body merely as irritants, but that they have some more direct effect upon the nervous system, for we cannot attribute the fatal event in this instance to the gastritis, which was neither general nor very severe, and which could scarcely have caused death in so short a time; that is, supposing the poison to have been taken the night before, after the deceased had discovered his loss. Again, there was neither vomiting nor purging, but, on the contrary, the poisonous solution seems to have remained quite at rest in the stomach, and thence propagated its influence, of whatever kind, which proves that it has rather a sedative

effect than an irritant, the latter being usually attended with vomiting and diarrhœa.

The mode of death also, by syncope or coma, which (if we may judge from the deceased's position, &c.) seems to have been free from severe pain, leads to the same conclusion.

PARTICULARS
OF A
CASE OF MILKY URINE.

To the Editor of the Medical Gazette.

SIR,

IN the Number of the MEDICAL GAZETTE for Oct. 27th there is a case of milky urine described by Dr. Golding Bird, who, in the same paper, expresses a wish for further information with regard to urine presenting oleaginous or milky characters. About the same time I was attending a case of anasarca with albuminous urine after scarlatina; and, as the fluid exhibited some unusual appearances under the microscope, I took notes at the time, in expectation that, scarlatina being then prevalent, I might meet with other cases with which I could compare it. In this I was disappointed; but thinking that the particulars I am about to mention may be interesting to Dr. Golding Bird, and others engaged in similar investigations; I submit them to you for publication if you deem them worthy a place in your journal.

October 7th, 1843, I was called to a boy, æt. 7, who was seized the day before with violent sore-throat, which was followed on the third day by the eruption of scarlatina, that proceeded regularly to desquamation. Before this process was completed, he exposed himself to cold, October 10th, and the next day the fever returned: the face was swelled, the abdomen enlarged and painful, with ascites, and dulness over the region of the liver, which protruded considerably from under the ribs. He also complained much of pain in the side of the throat originally affected. There was much cough, and even orthopnea; but I could detect no affection of the substance of the lungs, nor of the pleura nor pericardium, though the wheezing in the throat prevented an accurate diagnosis. Tongue furred; bowels confined: urine muddy, greenish, coagulating by heat; skin

hot and dry; pulse 180. He had calomel and squills, with a saline diuretic mixture.

The urine, when examined the next day, was of sp. gr. 1014. Under the microscope it exhibited nucleated globules and amorphous particles, both of various dimensions; but I was more particularly struck by the appearance of numerous bodies, evidently possessing the same composition, though of different forms and sizes. The most perfect resembled a single *cheval de frize*, or calthrops of six spikes, the nucleus or central boss of which was translucent, the spikes being sword-shaped and transparent, which I cannot better compare than to splinters of glass stuck into a ball of gum-arabic or mastic. None had more than six spikes, and some had only one; nor did the spikes appear to transfix the nucleus, but rather projected from it in various directions. There were no nuclei without spiculæ, nor any spiculæ unattached to nuclei. Nitric acid produced no change whatever upon any of the bodies, but liq. potassæ immediately dissolved the nucleated globules, the spiculæ with their nuclei, and some also of the amorphous particles. As the urine dried on the glass, the solid matters assumed a filmy appearance, interrupted by crystals of a circular and sword-shaped figure. Sometimes one or more of the arms of the sword-shaped figures were longer than the rest, and some of the circular figures were divided into four, five, or six portions.

A few days afterwards I procured some more urine, when some improvement had taken place in the symptoms; but I was not able to examine it for two days, by which time it had become very alkaline, and had deposited much lithic acid red sand, in the form of mulberry-shaded grains under the microscope. Neither nucleated globules nor calthrops were discoverable in this specimen, but there were quantities of amorphous particles, and numerous oily globules floating on the surface.

A third quantity of urine contained quadrangular, pentagonal, and hexagonal crystals, with bevelled or sloping sides and edges.

After this, the patient discharged blood from the nose, bowels, and bladder. The urine was loaded with colouring matter of the blood, and was only 1016 sp. gr. Its sediment

exhibited lithic acid and amorphous particles, but no oily globules.

Nov. 9th.—The boy is now recovering; and yesterday his urine did not coagulate with heat.

11th.—Urine yesterday was 1012·5 sp. gr. There is still some ascites. In a few days afterwards he was discharged cured.

From the effects of the reagents employed, I conclude that the various forms of crystallization were constituted by modifications of lithic acid and muriate of ammonia, particularly as the sword-shaped crystals bear considerable resemblance to the arborizations of the latter salt; but it is difficult to ascribe an origin to the oily globules.

A putrid specimen of the bloody urine, which I have examined this evening, gives to view, when dried on the glass, vast quantities of epithelial scales and amorphous particles, but very slight, if any, indications of oily matter.

I am the more induced to believe the sword-shaped crystals to be muriate of ammonia, from observing that dried saliva not only exhibits the beautiful arborizations of this salt, as figured by Raspail (plate 6, fig. 12, *Chimie Organique*), but also imperfect sword-shaped crystals.

In conclusion, I shall feel obliged if any of your correspondents will inform me where I may meet with figures of organic salts, &c. as exhibited by the microscope.—I remain, sir,

Your obedient servant,

T. OGIER WARD, M.D. Oxon.

21, Lower Phillimore Place, Kensington,
February 21st, 1844.

CONTRIBUTIONS

TO THE

PHYSIOLOGY OF THE HUMAN OVARY.

By CHARLES RITCHIE, M.D. Glasgow.

(For the *Medical Gazette*.)

[Continued from p. 634.]

PART I.

SECTION III.—*Cases in which menstruation, although commenced, had never been regularly established, the individuals not having had children.*

1. ELIZABETH C—, aged 17½ years; died of typhus about the fourteenth day. General health not good; menses irre-

gular, but present at commencement of fever. Ovaries large. *First ovary* was destitute of cicatrices, but marked throughout with dark, blue-coloured points, some as large as pin-heads, and others smaller, proceeding from Graafian vesicles under the peritoneal coat; also by one minute scarlet-coloured puncture, in which the peritoneum was as if newly perforated, and by another similar but less recent. Inner surface of gland very fleshy, vascular, and thick, and occupied by vesicles varying in bulk from that of a small dried pea to a pin-head; the vessels in some of them loaded with dark blood. No vestige of a coagulum, yellow, or white body. *Second ovary*: outer surface smooth, and without cicatrix. Size constituted mainly by one overgrown vesicle, with deeply congested coats, and by three or four others, some of which were as large as garden peas. No vestige of any rupture having ever occurred was noticed.

2. Marion K—, aged 18; in delicate health for two years, and menstruated only once, six months previous to death, which was occasioned by typhus fever. Ovaries plump, large, and smooth, being marked only by a few puncta, one of which was recent, and of size of a pin-head. No small vesicles had penetrated to exterior of peritoneal coat, but at one part this membrane was getting thin for about the size of a split pea, over an enlarged ovisac*. Inner surface of both ovaries turgid with vascular vesicles, some of which were just beginning to penetrate the inner surface of the peritoneal coat; of the size of mustard seed, and many others as large as peas. No trace of a clot, yellow or white body.

3. —, aged 19, and robust. Had menstruated three times only during life, the last time being only three months before her death, which was occasioned by fever. Ovaries large and plump, and marked by one linear scar only, which was also faint and doubtful; but their surfaces were roughened with innumerable very minute vesicular elevations, some of which appeared to have burst, leaving shallow open puncta, while, under the peritoneum, were some dark

* The term ovisac is used throughout this paper as a synonym of the Graafian vesicle or follicle.

coloured ovisacs, making their way to the surface. The interior of both glands was literally crowded with Graafian vesicles of various sizes, many extremely vascular; and corresponding with the external linear scar were the remains of a light fawn-coloured vesicle, all attempts to wash off the colouring matter from the inner surface of which were fruitless; a membrane of considerable consistence, which could be cut, and raised with the blow-pipe, being interposed. Enclosed within the laminae of the broad ligament connecting the ovaries with the tube, and also in the same situation, but suspended from the ligament by long delicate pedicles, were several vesicles, which contained a granular fluid having molecules, described by Dr. Andrew Anderson, who examined it, as resembling altered blood globules, but not containing any structure like an ovum.

SECTION IV.—*Cases in which menstruation had continued regular for a longer or shorter period, but had been suppressed for some time before death, the women never having had children.*

1. Charlotte B—, æt. 25, a house servant of good character. Menses irregular; was chlorotic, and died of typhus. Uterus small, its walls slender, a minute polypus projecting from inner surface of orifice. Labia healthy.

First ovary, plump and thick; four reddish vesicles of minute size jutting through the peritoneal coat; imperfect remains of three cicatrices with sub-jacent yellow cysts, one of which could have contained a small dried pea, and had a loose, pulpy, brain-looking inner surface, with a white shining exterior; the others reduced to a smaller size, but exhibiting a white stellated central line, surrounded by serrated yellow matter. A number of small unbroken Graafian vesicles were observed near the surface, and also two small, empty, white coloured cysts, with their coats considerably thinned.

Second ovary contained an immense number of minute vascular Graafian vesicles, some of which were projecting on its external surface, and two had burst, forming red puncta. There were present also the remains of four yellow bodies, one of which was intersected in its long diameter by a central

line, consisting of the walls of the cyst agglutinated by a thin film of opaque whitish tissue; which might either be its lining membrane or lymph. One white, fatty, or cellular-looking hollow body in ovary.

2. ——. Died of a chronic disease. Ovaries small, triangular, and marked externally with old cicatrices which were become faint, and with about a dozen of very minute vesicles, and some points, which were similar vesicles recently abraded and discharged.

3. Mrs. P—, aged 34 years. Died of empyema, and had not menstruated for some months. Known to have had no child. Ovaries of good size. First ovary strongly fissured on its free edge by old cicatrices. No recent scar, but whole surface sprinkled over with clusters of minute vesicles, some as large as a pin-head, their contents fluid, and escaping on being punctured; others seen only by means of a weak magnifier, and gritty, as if the liquid in them had become inspissated and hardened. Inner surface of gland plump, but pale, without any appearance of Graafian vesicles except two or three near the surface, recognized with the magnifier. No yellow substance, but four distinctly marked globular white bodies, chiefly of small size, but capable of being rolled out from their respective situations, were observed.

Second ovary exhibited a few faint fissures in its surface, the indications of former cicatrices, and also one or two fluid vesicles of minute size, but was very generally covered by points so small as scarcely to be seen by the naked eye, grating against the edge of the lancet, and having some resemblance in colour, transparency, and consistence, to crystals of candied sugar. Some of these could be turned out of the shallow cup-like depressions of the peritoneal coat in which they were seated, and rolled about under the finger, or caught on the point of a lancet, and when exposed to heat they shrank and became solid. Inner surface of ovary plump, with several pale vesicles, one being as large nearly as a hemp-seed, and in the peritoneal covering; also, a very white, corrugated, granular looking body, of about the size of a hemp-seed, situated near the free edge of the ovary, and having a pearly, shining inner surface.

Cases in which positive information respecting the recent suppression of menstruation is not recorded, but which are believed on various good grounds to have been of this kind, the parties not having had children.

4. — Hawkins, aged 20, a prostitute. *First ovary* covered, in more than a half of its exterior, by adhesions of the tube, and occupied by two or three obscure appearances of scars, and by four or five small vesicles, similar to those observed in children, and having the peritoneum covering them much attenuated. Inner structure of ovary contained a number of small, pale, unbroken Graafian vesicles, some of which were near to the surface; and in the centre of the gland two or three were found empty, and having their coats, which were of very delicate structure, stained of a deep black colour, but without any observable cicatrix or opening in the outer surface of the ovary connected with them.

Second ovary surrounded along its whole circumference by adhesions of the tube. Gland smooth, and without cicatrix. Two small pale ovisacs projecting like blisters from periphery; these were situated in the thickness of the peritoneal coat, having its inner aspect as their inner, and its outer as their external covering, just as under puberty. Two or three small, empty, attenuated nuclei, having their coats dyed black, and without any corresponding cicatrix, were seen in the centre of the gland. No yellow or white bodies in either ovary.

5. —, aged 19. *First ovary* exhibited, externally, nine cicatrices, all closed and smoothed over as if from age, and several blue macules, which, on opening the gland, were seen to proceed from the presence under the peritoneal coat of unbroken Graafian vesicles, while near to some of the scars were small gamboge or ochre coloured cysts, with pellicular coats, and no appearance any where of white corrugated bodies.

Second ovary had three scars of old date, and five vesicles, some of them projecting through outer coat. In the centre of the gland was a cyst without any seen opening from it, the walls of which were thin but melanotic, and contained some fibrin of a high gamboge colour; also a small fabiform cyst near the surface, with a

thick corrugated outer coat of a deep rhubarb colour. In this the colouring matter could not be lifted out like effused fibrin, and it was arranged on the interior with all the regularity of an organized substance; but no internal membrane could be demonstrated. Some obscure appearances of four or five white bodies.

6. —, aged about 25, and supposed to have been a prostitute. Os uteri circular and small. *First ovary*: exterior white and polished, with the exception of one or two circular shaped puncta, and interior contained only a few small and pale ovisacs. The *second ovary*, with the parillon and about half of the tube, were enclosed in a covering of broad ligament. Near to the edge of the tube, but more than half an inch from the ovary, a moveable hard tumor of about the size of a raisin was discovered, and, till exposed, was supposed to be the ovary. It was easily enucleated, having no organic adhesion except at one end, where it was bound by a pedicle, and was found to be a hollow cyst of very white cartilaginous tissue, of an irregular oblong or kidney shape, having a scabrous, indented, or fissured, and convoluted surface. It was three, or perhaps four lines in thickness, and could not be separated into laminae, although its outer surface seemed covered here and there with a delicate pellicle. Its inner surface, which was deeply fissured, was painted with a bright yellow substance, of the consistence and appearance of inspissated honey, which having no interposing pellicle, could easily be rubbed off with the finger. The internal cavity was as large as a garden pea, but reniform. The tissue interposed between this body and the ovary had imbedded in it a number of unburst vesicles of various sizes, having very pale coats. Interior of ovary also pale, with scarcely an ovisac apparent to the naked eye. There were no vesicles in the vicinity of the opposite ovary, the tube and ligaments of which were normal.

7. —, 45 years of age. One ovary much marbled with inky stains of various sizes, and of a circular form, having their centres constituted by a white spot, which might be a small sized cicatrix, or by a spiracular lesion of the peritoneum; and internally the gland was occupied chiefly by one very large ovisac, admitting of the demon-

stration of three coats,—one connected with the stroma, and the thickest, another pellicular, and the innermost so delicate that the fluid contents transuded by mere handling. The other ovary was covered with numerous shining solid points, something like the germs contained in the roes of the smaller fishes, and its interior was occupied by similar bodies, many of them, however, of larger size. They appeared to be ovisacs.

SECTION V.—*Cases in which the subjects had outlived the menstruating period of life, and were without children.*

Mrs. G—, aged 50. Uterus about one and three-fourths inches in length, but with all its parts symmetrical. *First ovary*: external surface nearly smooth to naked eye, but with a simple magnifier it was found occupied by numerous pores from which a transparent fluid escaped on pressure, and at one point there was a distinct minute vesicle, similar to those observed in children. Inner surface exuded transparent fluid freely when cut, and was occupied by numerous miliary vesicles, some observable with the naked eye, and vascular, others only with a magnifier, and destitute of red vessels. *Second ovary*: outer surface smooth, and free from cicatrices of ordinary kind, but occupied by about a dozen minute vesicles, some easily observed with naked eye, and others with the magnifier, and also by several pores or capillary sized puncta, which appeared to proceed from vesicles of the same kind which had burst and discharged themselves. Inner surface of ovary sprinkled with many very small Graafian vesicles, but no appearance in either gland of any yellow or white body.

2. Mrs. —, aged 70. No linear albicantes anywhere, or fissures in os uteri. *First ovary* size of a large kidney bean, smooth, and of a very white colour, without cicatrices, but having two distinct blisters or vesicles, each of the size of a small segment of a pin-head, and filled with fluid. Interior of gland exhibited two distinct whitish-yellow, fatty-looking bodies, of size of a large hemp-seed, with traces of some others; and, in addition, various slender globular shaped Graafian vesicles (best seen with a magnifier), which were filled with transparent

fluid. *Second ovary* of similar size, but more irregular shape; surface white, with exception of three or four vascular points, at one of which there was an indistinct appearance of a minute pellicular vesicle, and at another of a punctulated solution of the continuity of the peritoneal coat, and from the surface of this as well as of the first ovary a transparent fluid exuded on pressure. Inner surface occupied by many Graafian vesicles filled with their usual contents, some having their coats injected with red blood, but more generally white; and, at one point near the periphery, there was an appearance as if a vascular vesicle of about the size of a pin-head had burst, and had blood effused into its cavity.

3. Christian M^cW—, aged 50. Hymen entire; both ovaries sunk in size, and deeply fissured and indented in all directions, by remains of cicatrices now representing lines, some occupying the whole length of the glands, and others their small diameter. The inner surface was vascular, without any traces of vesicles, yellow, or white bodies. The glands seemed to be absorbed to their fissured and corrugated peritoneal covering, lined with a thin vascular coating.

4. —, aged about 50 years. No appearance of having borne children. Ovaries much shrunk, and indented with cicatrices, corresponding to which were two or three whitish yellow points, of a miliary size, one of which was distinctly hollow, the structure soft and delicate. No Graafian vesicles present.

5. Examined the fallopian tubes of a woman aged 71 years. Air was made to traverse both, on application of moderate power, although, in one of them, with difficulty.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Natural History, Pathology, and Treatment of the Epidemic Fever at present prevailing in Edinburgh and other towns: illustrated by Cases and Dissections. By JOHN ROSE CORMACK, M.D. Edm. F.R.S.E. &c.

DR. CORMACK enjoyed excellent opportunities of studying the late fever in

Edinburgh, having been Physician to the New Fever Hospital, where he states that he reported "minutely" almost every case committed to his charge. He has also, since that time, daily devoted a large portion of his time to observing and recording cases; both as influenced by medicine, and when allowed to run their course undisturbed. His principal object is to present a faithful account of the natural history and pathology of the epidemic, together with the details of treatment.

The ordinary or moderately congestive form of the disease is thus described. The countenance of the patient has a peculiar aspect, of which our author endeavours to convey an idea by calling it "bronzed," but adds, that no words can convey an accurate idea of what is attempted to be described; which, however, is so characteristic as to have arrested the attention of all visitors to whom it has been pointed out.

A great similarity was observable in the manner in which the symptoms made their first attack. The patient was seized with coldness, rigor, headache, pain in the back, and prostration of strength; the latter symptom, however, being generally less urgent than in ordinary cases of fever. The cold fit has usually lasted from half an hour to two or three hours, after which the headache becomes more severe, with dry burning heat of the general surface, and urgent thirst.

The hot stage is followed by sweating, usually to a great extent, and lasting for several hours without producing any relief to the general symptoms. The perspiration has a very disagreeable smell, and is of marked acidity, deeply reddening litmus-paper.

Even during the first paroxysms the pulse is very frequent, sometimes reaching 150; wiry and tremulous during the rigors, but hard during the hot stage; although when the sweating has set in it becomes fuller and softer.

During the first 48 hours the tongue is commonly white, yellow, or brown, but moist, "excepting at the point, where there is usually a clear space, extending over a space often shaped like a triangle, the extremity of the tongue forming the base."

During the first few days some of the patients have occasional returns of rigor, but more generally they are in a

state of dry burning fever, partially relieved by occasional sweating.

Nausea and vomiting attend a considerable number of cases during the first few days, even although they do not prove ultimately severe: these symptoms are usually attended by pain at the pit of the stomach.

Muscular pains of severe character uniformly attend the onset of the disease, and last for several days. Pain about the abdomen, more especially over the liver and pubes, are also very common.

Sleep is generally banished by the sufferings above detailed, and is only to be procured by means of opium.

A remission generally took place on the third day: nay, the author adds, "it occurred in all the cases which I have had an opportunity of attentively observing from the invasion onwards."

On or about the fifth day there was generally an evident manifestation of the disorder abating, and often the improvement was both sudden and complete, the favourable change being for the most part ushered in by some discharge, as sweating, epistaxis, or diarrhœa.

After this, the pulse, tongue, and skin become entirely natural, and the "bronzing" of the face begins to disappear.

From this time the patient improves, progressing till the fourteenth or fifteenth day, when there usually occurs a relapse, marked by a paroxysm of fever similar to that which attended the first attack. Sometimes this second attack is more severe than the first, but commonly the reverse is the case. In those who are pregnant, abortions now frequently take place, and in the more unfavourable cases, jaundice, delirium, diarrhœa, dysentery, and other severe symptoms, supervene.

In not a few cases a second relapse occurs about the 21st day. After this, in those who are strong and of good constitution, the recovery is rapid and complete; but in the old and debilitated, the improvement is very slow; nevertheless the epidemic, upon the whole, has been very far from a fatal one.

Various cases are detailed, in which, however, we do not think it necessary to follow our author, but proceed to the second form, designated the "highly congestive." In this one of the most common symptoms is the yellowness

of the conjunctivæ, and, indeed, of the general surface of the body. This appears between the third and seventh day, and is most intense upon the face, neck, chest, abdomen, and thighs. The urine becomes as dark as porter, and the stools absolutely black, with an obvious admixture of blood. Together with these discharges there is vomiting of "coffee-ground like" matters.

As indicative of cases being destined to present these unfavourable symptoms, the countenance early exhibits a deep persistent purple colour, by which the future severity of the case may be foreseen.

In the severe cases there is generally a *remission*, but not amounting to an *intermission*, about the seventh day.

On post-mortem examination excessive capillary congestion was always met with in the intestines, and occasionally even an exudation of blood between the muscular and mucous coats of the intestines.

Taking in connexion all the peculiarities of the epidemic, the following appear as the positive and negative characters which it presents.

1. The sudden and violent invasion of the disease.

2. The bronzing or purpling of the countenance.

3. The almost uniform occurrence of one or more relapses.

4. The large proportion of cases presenting the phenomena of yellow skin, black vomit, and hæmorrhages.

5. The short duration of the pyrexial state, and its mode of terminating.

6. The severity of the muscular and articular pains.

7. The severe vomiting, with the accompanying affections of the liver, spleen, and bowels.

The fever has also presented some sequelæ which deserve notice: the first, and one of the most remarkable among these, is a peculiar form of "ophthalmitis," generally preceded by amaurotic symptoms. This bears a resemblance, in some of its characters, to rheumatic ophthalmia, and is extremely similar to that described by Dr. Mackenzie, of Glasgow, in this journal (November 24th), as following the fever lately prevalent in Glasgow; and also by Dr. Jacob, as having occurred in Dublin in the fever of 1826.

We come now to the *treatment* of the disease, on which we find some

judicious and instructive remarks. The author recommends that we should be "ever *ready* but never *hasty*" in our interference, endeavouring to guide our patient safely through a course which he must pass, rather than to arrest his progress by *heroic* means.

The evils to which a tendency is manifested, and which it is our chief business to guard our patient against, are—

"1st. Congestion of the mucous membrane of the stomach and intestines, terminating in effusion of blood, and subsequent destruction of large portions of this tissue.

"2d. Congestion of one or more of the abdominal viscera, particularly of the liver and kidneys, disabling them from the performance of their secretive functions, thereby causing bodies to circulate with the blood which ought to be separated from it, and which bodies we know act as poisons when not so eliminated from, or when directly introduced into the circulation.

"3d. Debility and sinking.

"4th. It will also be necessary to speak of the measures to be adopted to prevent or modify relapses."

The steady use of purgatives cautiously administered, and determining the blood to the surface, are the means recommended to obviate the first of these evils. In some cases blood requires to be abstracted in small quantity. When the kidneys are not acting efficiently a small quantity of blood is to be taken from the loins; or even dry cupping practised, if the debility be great. In this last case cordials and stimulants are recommended.

To be more particular—few bore the loss of more than ten ounces of blood, several becoming affected with vertigo and faintness after losing only two or three ounces. Some, while the blood was flowing, declared that the headache and vertigo had quite left them, but were suffering as severely as ever within half an hour after the arm had been tied up. Much more effectual relief was afforded by the operation of a purgative, a warm foot-bath, and cold lotions to the head. In several cases in which there was pulmonary inflammation, the symptoms speedily disappeared under the use of antimony and morphia, or morphia and ipecacuanha. And the same remedies, combined with counter-irritants (sinapisms or blisters),

are represented as safe substitutes for bleeding in thoracic complications!

"As the result of my experience (adds our author), in this matter, I would say that the cerebral, pulmonary, and abdominal complications in which it is proper to abstract blood are extremely rare, and that in very many such instances it is a most hazardous practice." Some of the most severe and threatening cases of abdominal affection, with pain and tenderness of the most urgent nature, were safely treated by means of the diligent use of warm fomentations and poultices. Enlarged spleens have also done well under the use of the same means. Medicines which act upon the skin were most resorted to the first fortnight, (such as *Liquor Acetatis Ammoniae*, James's powder, Antimony, and the *Pulv. Ipecac. Comp.*); but all these were afterwards abandoned, as it was soon perceived that those who did not take them sweated as copiously as they who did.

Sponging with hot and tepid water was generally found to be useful, and bathing the feet in hot water tended remarkably to allay restlessness. Poultices and warm fomentations were also very serviceable in the abdominal complications.

Cold to the head, if diligently used, was of great service in the cases where headache was urgent. Cold was also applied to the surface generally or partially, according to the general or local nature of the heat; but caution was used in this respect, as where the skin was not very hot and dry the cold applications did harm.

Warm drinks early in the night disposed to sleep, and were given as soon as quiet was established in the wards.

Cold drinks were only allowed with caution, as they were otherwise found to excite pain in the stomach, and vomiting.

Purgatives were cautiously but steadily used, and with most important advantage. The object kept in view was merely to empty the bowels, without producing any thing like catharsis. Compound powder of jalap, compound colocynth pill, and calomel, were the purgatives chiefly used. When there was much flatulence (which is said frequently to have been the case), the aloes and assafoetida pill is represented as having been given "with the best possible effects."

Enemata were also given when necessary to evacuate the bowels; but the more stimulating cathartics were never used except where there was an appearance of comatose symptoms about the head. Castor oil is favourably spoken of as producing effectual evacuations without irritation. Medicines which act on the kidneys were employed with advantage when the urine was particularly scanty and scalding. The chief ingredients of this kind were Nitrate of Potass, and the Spirit *Etheris Nitrici*, with warm fomentations, and in severe cases cupping on the loins. When alarming head symptoms supervened, the author gave especial attention to the kidneys, from the idea that the urea not being properly eliminated, was acting as a poison on the general system. In order to check vomiting, opium was the medicine chiefly used in one or other of its forms, and one expedient particularly commended in such cases is a drachm of the solution of muriate of morphia as an enema. "Vomiting of the most urgent kind, when nothing is retained on the stomach, is sometimes checked and most commonly moderated by this means."

Mercurials are spoken of with very qualified commendation. The "tolerance" of this medicine in fevers, it is remarked, is very great; but it is added, that when salivation occurred it was always simultaneously with, and not as a forerunner of, returning health.

To relieve the muscular and arthritic pains, colchicum was tried, but no relief could be observed to flow from its administration, though given both in large and small doses. The hydriodate of potass was supposed to afford relief, sometimes; the pains seldom yielded under any treatment till the strength returned, but some benefit resulted from friction with a liniment of soap and opium.

Tonics were very useful during the intermissions, and in the convalescence. *Cusparia* or *cascarilla* was that generally chosen by our author with which to commence, after which he went on to the mineral acids and sulphate of quinine. In those previously given to drinking, quassia seemed to answer best. Port and sherry wines are considered as the best of all the tonics, but were comparatively little used, owing to their expense. Sulphate of

quinine seldom prevented relapses, and is not highly spoken of.

The little volume before us, of which we have extracted the essence, is highly creditable to the author, being a very unassuming account of the epidemic lately prevalent in Edinburgh, and containing a great deal of useful information, evidently the result of careful and intelligent observation.

MEDICAL GAZETTE.

Friday, March 1, 1844.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

THE COLLEGIATE SYSTEM.

It is always gratifying to a journalist to shew that his predictions have been fulfilled; and his gratification is still greater when it appears that, in foreseeing the possibility of some great improvement, he has absolutely indicated the road to be pursued, and removed difficulties from the thorny path of reform.

It is, therefore, with particular pleasure that we refer to our article on Medical Colleges, written nearly three years ago*. What was then a hope is now a fact; the *venue* only is changed; for what we expected at Guy's has taken place at Bartholomew's. More recently, indeed (June 16, 1843), we commented on the scheme then in full preparation for the benefit of Bartholomew's; and our anticipations have been verified, we believe, to the very letter.

The six houses in Duke Street, which we spoke of, have been turned into chambers for students, after having been altered and repaired during the summer months. A dining-hall and kitchen have also been built; and it is expected that students should dine in

the hall, unless notice to the contrary is given to the manciple in the morning.

The weekly terms are:—

	£	s.	d.
For each student in rooms on the first and second floors	1	15	0

For each student in rooms on the ground and third floors	1	12	0
--	---	----	---

For two students occupying one sitting room, with two bedrooms, each . . .	1	9	6
--	---	---	---

These sums include rent, provisions, attendance, coals, and candles.

The daily meals are three in number, namely, breakfast and tea in the students' rooms, and dinner at five precisely in the hall.

The provisions are sent from the Albion Tavern, in Aldersgate Street.

We have dwelt on these terrene matters with minuteness, as they are of considerable importance, and a previous knowledge of the state of things may save some trouble to our younger readers, and their friends, in distant parts of the empire.

And now for one or two points of discipline.

Prayers are read every morning in the hospital church; many students are there, but attendance is not compulsory.

Friends who visit students are to leave their rooms by 11 P.M.; the students themselves must be home by 12; and no one is to be absent during the night without permission of the warden.

The maintenance of these useful rules will depend in part on the firmness of the present sensible and judicious warden, Mr. Paget, and, in part, on the zeal with which he is supported by the governors. Should a black sheep ever arise among the flock, he must, of course, be expelled without delay:

Ense recidendus, ne pars sincera trahatur!

The plan has now been in operation since October 2d, and works admirably.

The sets of rooms are twenty-five in

* MEDICAL GAZETTE, April 2, 1841, page 71.

number; and as twenty-three are occupied, and there are applications for the other two, the College may be considered full. We earnestly hope that, ere long, the College may be considerably enlarged; and that so fortunate a hospital, rich in lands and houses, will extend an acknowledged good to a greater proportion of its students.

One obvious advantage which the students enjoy is that of adjoining the hospital.

Another is that of having their professional studies superintended by a man of zeal and knowledge.

A third advantage, which we see in the dim future, through the long vistas of time, is the foundation of a real medical school:

Nascere, magne puer!

A school, in short, where as much pains should be taken in teaching the art of healing, and its ancillary sciences, as are now elsewhere bestowed in teaching the ancient and modern languages, or the pure and mixed mathematics.

Let us consider how this is to be done.

It may seem a paradox to assert that the essence of genuine teaching consists rather in the pupil's repeating the thing to be learned to his tutor, than the converse; yet so it is. The young Etonian does not learn Horace so much by having it explained to him, as by himself explaining it to his teacher. And this holds good with all the branches of knowledge which are generally taught with success. If you want to know the subject thoroughly, you must construe, or demonstrate as well as you can, and submit to have your mistakes corrected by your master. The task is toilsome, but necessary, and no learner, whatever be his age, is exempt from it. Suppose, reader, that being now a middle-aged man, you wished to acquire German. Do you think you could effect your purpose by

hearing a professor from Berlin or Göttingen lecture on the language and literature of Germany? *Minime gentium*. You must go to Dr. B., and by taking 100 lessons would attain your object better than if Schiller and Göthe had risen from the dead to lecture at the Hanover Square Rooms. The reason is plain enough. The student who hears the lectures on German is in a reverie half the time, and during the other half acquires no practical knowledge of the thing wanted. The student with Dr. B. works his way through a *Lesebuch*, writes some quires of exercises, and talks that language on the banks of the Thames which he hopes one day to speak on the shores of the Elbe and Rhine.

It is just the same with other things. Could a Cambridge man learn any part of mathematics, from the lowest to the highest, from Euclid to Laplace, by merely hearing it talked about? Certainly not. He works the problem with, *i.e.* to a tutor in the lecture-room, and often to another tutor out of the lecture-room.

Could a scholar in the fifth year of his age learn the criss-cross row, or the genuine method of spelling a polysyllable, by an *ex-cathedra* lecture? Certainly not.

In our article of April 2, 1841, we remarked: "From no small experience, we are convinced that one of the greatest difficulties the student has to contend with is his ignorance of how and what he is to study—a difficulty so great that the majority even of those best disposed to work utterly lose their first three or four months in trying to find out what they should study, or in a vain attempt to study every thing, or in learning that which they had far better postpone to a later period. And even when one does hit upon the right object of pursuit, it is no easy matter for him, if his mind have not been more than

commonly disciplined, to determine how he should study, or to decide from time to time how much he knows, and judging from his past progress, to tell what his further course should be."

Every one will readily acknowledge the truth of this picture, and every one will equally confess that these difficulties could not occur in a real school of any kind. From the University of Cambridge down to the humblest suburban academy, no student can be at a loss to know what he is to study. The lesson is a known tangible thing, not a vague possibility. Yesterday, for instance, the freshmen in D. College got to v. 904 in the *Medea*, and Book III. Prop. 4 in *Euclid*; to-day, therefore, they will begin their construing and demonstration at v. 905 of the former, and B. III. Prop. 5 of the latter.

Precisely the same thing might be done with any decent text-books in anatomy, physiology, or the practice of physic.

But some one will object, "how are the class to understand the preparations and plates necessary for the illustration of these topics?"

Answer. Unless the pupils are very far advanced, the professor will give a short explanation of these adjuncts on the day the lesson is set, just as a professor of a science or language occasionally does; and on the next day, when the lesson is repeated to him, he will clear up the remaining difficulties by a luminous commentary.

It is true, and a curious psychological fact it is, that a boy may pass through Eton or Harrow without acquiring any but the most superficial knowledge of the languages he is supposed to learn there. Yet even this smattering is probably more than what is obtained by the student who sits in a dreamy state at a lecture which is not a lesson. He who had been obliged, day after

day, to give his teachers a *vivâ voce* account of the function of digestion, the symptoms of pericarditis, and so forth, from the text-books of the school, would rarely present himself for examination at Hall or College as a complete vacuum of knowledge. The speedy appearance of clear, well-defined text-books, would be one of the minor advantages to be derived from this reform.

Before concluding, we will add that the adoption of the collegiate system in the medical school at Birmingham was warmly advocated by the Rev. Vaughan Thomas, about a year ago. His pamphlet, which shows great zeal in the good cause, was printed for private distribution only.

The existing College at Bartholomew's, and the one at Birmingham which ought to be called into existence, have our heartiest wishes for their success.

A LATE INQUEST

IN THE BRIDGEWATER UNION.

WE wish that we could call the following case a remarkable one. It is to be feared, however, that it is rather an example of a rule, than an exception to it; and that the history of poor Mary Ann Evans is merely a sample out of a multitude—an exemplification of the fate of those for whom, in Malthusian phrase, there is no place at Nature's table.

In the beginning of January last, Mary Ann Evans, aged 14, was taken from the Bridgewater Union Workhouse, as a servant to a Mr. Waterman, of Spaxton. At this time she appeared dull and stupidified, but was thought to be in good health. No further account of her health is given until Saturday, the 17th of February, when she was already in a desperate state. Mr. Waterman then desired a carrier to take her back to the Union House, which was accordingly done in a cart without springs. The unfortunate patient was suffering from pain in the left side and knee. When the cart moved, Evans complained of great

pain, and cried out "stop, stop." The driver stopped for five minutes; but Mr. Waterman then allowed the cart to proceed. The pain in her knee was increased by passing over the stones, and the cart went very slowly on her account; so that, if the time is rightly given in the narrative, a journey of five miles occupied three hours. On arriving at the workhouse she was worse; and when the people of the house came to carry her in, she said "I cannot bear for you to touch me. I won't let you touch me."

Mr. Abraham King, surgeon to the Union, was immediately sent for, and bled her on his arrival. The next day he saw her twice, and bled her again in the evening; on the Monday morning she died. Mr. King thought her case a hopeless one when he first saw her. On a post-mortem examination, several ounces of serum, containing lymph, were found in the pericardium; the knee-joint was distended with pus, and the thickening of the membranes shewed that the disease was of some weeks' standing. Mr. King was decidedly of opinion that the death of M. A. Evans was hastened by her removal.

The jury brought in the following verdict:—"Died by the visitation of God; but the jury think that a deal of blame is attached to Mr. and Mrs. Waterman for their negligence in not applying to a medical man, and the deceased's death was greatly accelerated by the removal." (Times, Feb. 24th, 1844.)

This case of domestic neglect and cruelty shews almost white, when contrasted with many of the dark histories registered against the New Poor Law. It is an instance of a system of ill-treatment which one need not go to Somersetshire to witness—the overworking of friendless maid-servants in *mediocre* families. They are worn-out, used-up, and then sent to perish where they may.

"I have seen West-Indian slavery," said a philanthropic writer, "I have seen the labours of galley-slaves; but I have seen nothing like the slavery of a servant-of-all-work in a London lodging-house!"

DEATHS IN CHILDBIRTH.

In the four years, the returns under this head were less specific than could be desired.

The amixed return of some cases occurring in the metropolis will, however, give a general idea of the nature of the accidents that render childbirth dangerous.

Of 196 cases noted, 55 were returned simply as "childbirth;" 7 "miscarriages," two of the latter attended by hæmorrhage; 27 "flooding," or loss of blood; 6 rupture of the uterus; 63 puerperal fever, peritonitis, or inflammation of the womb; 1 erysipelas; 1 inflammation of brain, 1 of heart, 4 of lungs; 3 phlegmasia dolens; 1 serous effusion after childbirth; 14 exhaustion, collapse, syncope, debility; 2 convulsions; 5 puerperal mania; 1 difficult labour; 1 exhaustion from a fibrous tumor in the uterus; 1 tubercles in the womb after childbirth; 1 ovarian dropsy after premature parturition; 1 dropsy and childbirth.

Original malformation renders labour in some cases difficult and dangerous; at other times pregnancy occurs in women afflicted with fatal diseases (fibrous tumor, tubercles, ovarian dropsy); and, as childbearing does not exempt the frame from disease, all the deaths which occur in that state, spontaneously or from accident, must not be ascribed to it in any other way than as a complication. Small-pox is almost invariably fatal in the puerperal state; and if inflammations of the brain, heart, and lungs, occur, their danger must be increased; but it is probable that the above cases were some of the many complications of "puerperal fever."

The terms—puerperal fever, puerperal peritonitis, uterine phlebitis, inflammation of the uterus—are applied by writers, without any great discrimination, to modifications of one affection, which it was proposed, in the nosology, to designate "metria," the uterus and its appendages being the source and principal seat of the malady; which has, however, no more in common with pure inflammations, like peritonitis, than the changes of the glands of Peyer in typhus. Metria is contagious; but this fatal disease, with phlegmasia dolens and puerperal mania, will probably be regulated, to a certain extent, by the same causes as diseases of the first class. Another large section of the mortality is from the loss of blood, rupture of the uterus, or mechanical causes, and must very much depend upon the skill and care of the persons in attendance.

A certain number of deaths are caused every year by the contagion of puerperal fever, communicated by the nurses and medical attendants; but this will be referred to shortly.

Midwifery is well understood in England, and the medical practice is certainly as sound, as little encumbered with obsolete prejudices, as well adapted to aid and correct the efforts of nature, as the other parts of surgery; but errors in practice are sometimes committed; and though excellent nurses, considering their education, are sometimes met with, medical precepts are too often set at nought by the nurses and old women in attendance, who have peculiar views of their own, which they lose no opportunity in announcing and carrying into effect, with the best intentions in the world, but the worst consequences. A large proportion of the 500,000 English women who lie in every year, and have any attendance at all, are attended by midwives, who, from one cause or other, probably delicacy of the national manners in points of this kind, receive no regular preliminary instruction in anatomy and other matters, some knowledge of which a glance at the causes of death in childbirth will show is indispensable in many emergencies. It is true that a medical man can be called in where the danger is imminent; but, to discover danger, knowledge is required; and those who have come in contact with midwives, or "monthly nurses," are well aware that ignorance does not diminish their self-confidence. In France, the "*sages-femmes*" go through a regular course of instruction, theoretical and practical. Madame Boivin and others have greatly distinguished themselves there by their writings, and contributed not a little to the progress of their art. Mr. Hoffman states that the Prussian Government supported, in each of the eight provinces, schools of midwifery, which in 1837, had furnished the country with 11,155 midwives, examined and passed by the Medical Boards.

It would be folly—with the undoubted differences in our manners and institutions—to argue that the French or Prussian systems should be introduced into this country; practically they are perhaps not more efficient than our own; but it is very well worth while, in the first place, to inquire whether our English system do not admit of essential improvements, and in the second, what steps should be taken for carrying these improvements into effect.

No one who has reflected upon the subject, and certainly no one who has a practical acquaintance with it, will contend that the annual deaths of 3000 women in childbirth, and of 13,350 boys, and 9740 girls in the first month after delivery, or the sufferings and deformity of those who escape with life, are natural and inevitable. Admit that the lives of a thousand—of five hundred—or of one hundred of these mothers could be saved—and that many more might be rescued

from injuries and pains which disable, or never leave them, and assuredly no apathy, no false sentiments of delicacy, will prevent those who have the public health at heart from giving the subject the most attentive consideration.

If schools for the education of nurses and midwives were established in the metropolis, and the large towns, under medical supervision, and some distinction were conferred upon those who proved attentive, kind, and skilful, such schools would probably be frequented. A highly useful profession would be thrown open to women, who have now so few sources of profitable employment; and the utility to the community, of a recognised body of respectable women, educated as nurses, acquainted with the plain doctrines laid down in the popular medical works on health, and possessing as much knowledge of midwifery as the French *sage-femme*, would be incalculable. Some of these schools might be connected with the present hospitals and lying-in institutions; others might be founded for the delivery of easy popular lectures, and for providing the wives of the indigent with gratuitous attendance, or attendance slightly remunerated—to be supplied by the young nurses, superintended by those practically versed in their art, and medical officers.

In a year, or two years, intelligent women would acquire, at such an institution, sufficient information and skill to be useful nurses. It is questionable whether they should be taught the properties of drugs. I do not think that they should be allowed to dabble in such dangerous articles. If they were taught in what circumstances to give a few drops of laudanum after delivery, and when to administer castor-oil, or tincture of rhubarb themselves, or in what way to apply the remedies prescribed by physicians or surgeons, it would be enough. To attempt more would be to establish a new class of half-educated practitioners, like the druggists, and would infallibly lead to mischief, without any chance or prospect of counter-vailing good.

After consulting on the subject several medical men in extensive practice, I may state that the want of good, educated, trustworthy nurses is felt in the highest circles, as well as in the middle ranks of society. The nurse is always present with the patient; the medical man only occasionally; to the nurse is intrusted the administration of remedies, the ventilation of the apartment, the warming, the diet, and a thousand nameless offices on which health and life depend. How can a nurse without any knowledge of principles—without sound convictions engrafted on her mind by education—swayed by her feelings and traditional prejudices, be

expected to discharge her difficult duty? The nurses of our hospitals acquire a practical knowledge of their art, and get employment out of doors; but, as a general rule, hospital nurses are under-paid, and the consequence is that they are too often a very inferior class of women, who can get no other engagement. There are exceptions, but as our religion has not yet called into existence a class like the *sœurs de charité*, it is vain to expect nurses to supply their place, unless the wages (they should be salaries) be sufficient to supply educated persons with a comfortable subsistence.

An institution for the education of nurses would probably succeed better than many of the medical schools; but they would be nurses for the middle and higher classes; the small outlay of capital which an education of the kind would involve, must tend very much to preclude the admission of midwives for the poor labourer's or the artisan's wife. To provide these the professional education should probably be at first gratuitous; or a few professorships might be endowed, and the fees be made low for all the instruction in the doctrines of health, and the principles and practice of midwifery, including nursing in sickness of every kind. The appointment of parish nurses and midwives under the medical officer, could alone provide for paupers; but the labourer or artisan would find the attendance of the nurses, who had availed themselves of the moderate education adverted to above, of great use in the sickness of his wife, and really less costly than the spirit-drinking nurses now met with, who sometimes demoralize the mother, and poison his children.

Several collateral advantages would arise from the institution and support of a class of educated nurses distributed all over the kingdom.

New habits and practices are much slower in their progress than opinions and knowledge; they require to be taught "in season and out of season"—by precept and example. Our present knowledge of the laws of health—of the causes of death, and consequently of the means of preserving health—is imperfect, no doubt, but is very far in advance of what was possessed in the last century. The popular works of Dr. Southwood Smith, Dr. Andrew Combe, Mr. Pye Chavasse, Dr. Hodgkin, and others, place within the reach of the public important doctrines which were unknown to Sydenham. Such popular medical literature has an extensive sale; but it would be a mistake to suppose that the mass of population, rich or poor, is acquainted with the best established sanatory principles, and the reasons on which those principles rest,—is therefore much influenced

by them, or is willing to take the trouble and incur the expence requisite for procuring what science and calculation prove are necessities of life. The practice of no small part of the population in sanatory matters, so far as it can be referred to rules, and is regulated by doctrines, is the practice inculcated by former generations of medical men; and is only broken in upon by a few rays of light. The well-informed part of the community owe their enlightenment principally to the teaching of their medical attendants, who lose no apt opportunity of laying down rules of health, and enforcing them, by drawing the attention of families to the sad and often striking consequences of neglect. This is the more praiseworthy in the members of the medical profession, considered as individuals, inasmuch as the colleges do not prescribe, nor the schools provide, as in other countries, any systematic courses of instruction in hygiology (the *hygiène* of the French). The art of preserving health is not yet taught in the medical schools of England; and it is only just to add that it is not paid for in any shape by the public.

It is nevertheless to the medical profession chiefly that we look for the sound doctrines of hygiology, and to their due influence in the homes and daily life of families. But would not the medical man be as much assisted by instructed, as his proposals are thwarted by ignorant, nurses? Would not the constant reasoning, the stories, the advice, of an amiable woman—comparatively well instructed in her *profession*—go further than anything else to inform the minds and to impart practical principles to the mothers of families? And who does not know that the comfort and cleanliness of the poor man's hearth, the lightness and health of his room, the vigour and training of his children, are the work almost entirely of the wife. If the educated nurses possessed the sound common sense and good nature which a body of English women scarcely ever wants, and could be induced to read so as to keep up their knowledge, and to apply practically the improvements which every day brings to light, they would be a connecting link between the highest class of intelligences engaged in medical research, and the humblest members of the community to whose advantage those researches invariably tend. The English midwife would then beorthy fore reward."—*From the Registrar General's Report.*

THE METHOD TO BE ADOPTED FOR OBSERVING THE
CIRCULATION OF THE EMBRYO
OF A FOWL.

WHEN we succeed in preparing an embryo of from 30 to 40 hours, and in detaching it and extending without injury under water upon a slip of glass, and submitting it to the plate of a simple microscope, we observe at one time the whole vascularities and circulatory circles from the heart, which we see contracting and propelling the blood into the aorta, even to the extremities of the arterial divisions, from which the blood passes into the venous radicles, and from those radicles even to the larger veins by which it returns to the heart. It is only by a low magnifying power that we can observe the whole of this phenomenon at one time; but a magnifying power of about 100 linear is necessary in order to be able to examine the details.

When we wish to examine the embryo at different periods, it is necessary to separate the white, and carefully place the yolk in a small cup; this cup or glass capsule is to be placed in a vessel nearly filled with warm water; and if the germ is developed, we shall recognize the extent and capacity of the *cicatricula*. Then cut the membrane around the *cicatricula* circularly by the aid of a pair of fine scissors, and then detach the *cicatricula* by raising it carefully, and by drawing it delicately by means of a mounted needle; shortly it floats on the water, and after having taken out the little capsule with the yolk to disengage it from a part of the adhering yellow matter which interferes with its transparency, it becomes very easy to receive the floating and membranous *cicatricula* upon a slip of glass surrounded with water (a little cell covered with the thin glass would be better), where may be observed the phenomenon above alluded to.—*London Physiological Journal*.

TRACHEOTOMY IN THE LAST
STAGE OF CROUP.

At the sitting of the Academy of Sciences on the 8th of January, M. Scoutetten, Professor at the military hospital of instruction at Strasburgh, read a case of tracheotomy performed with success in the last stage of croup. He performed the operation on his own daughter, an infant six weeks old, to save her from imminent death.

The operation was successful. According to M. Scoutetten, it is the only instance of tracheotomy performed on account of croup on an infant of this age; and the only one in which such alarming symptoms lasted so

long. He is of opinion that this case ought to encourage the timid, and show the surprising resources of nature at this tender age.

MM. Roux, Breschet, and Serres were appointed to report upon the case.—*Gazette M dicale*, Jan. 13, 1844.

COLLEGE OF SURGEONS.

To the Editor of the Medical Gazette.

SIR,

IN the selection of names to receive the honour of the Fellowship, the Council has been most properly regardful of those who, although resident in the provinces, have taken a respectable local position in our profession.

The grand and safe principle by which they appear to have been guided is that of thus honourably marking those whose names appear as the medical officers of our provincial hospitals, taking such a position as the guarantee of local professional standing.

The main reason, and a most efficient one it is, for the institution of this new surgical rank, would appear to be that of exciting to the acquirement of a higher professional standard.

To the general excellence of the arrangements I must bring to your notice one most singular exception, viz. the absence from the list of every medical officer in the East India Company's service, with only two exceptions, and those in the persons of gentlemen who have retired from the east.

Surely, Sir, measured by the test which the Council has laid down, the officers of the general hospitals of the three presidencies, gentlemen filling the position of pure surgeons, and totally disconnected with pharmacy, might be deemed at least as worthy of the honour as many general practitioners attached to much inferior institutions, and with names perhaps still less known to fame, who have received it.

I have been told that the former, from their distant residence, cannot fulfil their duty as electors; but I maintain that the same difficulty will exist to a certain extent with the latter. Moreover, the chief object in forming this new grade is to confer rank, and encourage high attainments—the elective franchise is surely but a secondary object.

I trust, Sir, most anxiously, that in the forthcoming "batch," this serious injustice may be remedied as far as may be.

I am, sir,

Your obedient servant,
A BENGAL MEDICAL OFFICER.

Feb. 26, 1844.

A HANDSOME FEE.

THE father of Frederick the Great, of Prussia, "when his son had the small-pox, in great alarm despatched a messenger to Ellert, his physician. When the latter arrived, and relieved him from his anxiety about the state of the child, his Majesty, as a special token of his royal gratitude, and to compensate the Doctor for his attendance, ordered that he should be supplied, during his residence at the palace, with two bottles of Duckstein beer a day, and a dinner that was not to cost more than six groschen, or ninepence of our money."—*Campbell's Life of Frederick the Great.*

MODE OF EXTRACTING CALCULI FROM THE BLADDER.

THE following method of taking calculi from the bladder, without operation, is adopted by Dr. Aberle, at Reidlingen on the Danube (Wurtemberg), where gravel amongst children from one to four years of age is frequent. Dr. Aberle's treatment consists in relaxing the circular fibres of the bladder, which cross the external longitudinal or detrusive fibres, and gradually thicken as they approach the neck, and form the sphincter of the bladder. In the first case a calculus the size of a large pea was detected with a sound. An emulsion of hempseed, with extract of henbane, was given internally, and an ointment of belladonna rubbed on the perineum. Eight hours afterwards a calculus got into the urethra, and was expelled spontaneously. Fifteen other children, under the same treatment, have passed calculi in from 18 to 36 hours. The paralysis of the bladder lasted but a short time.—*Allgemeine Zeitung für Chirurgie*, &c. published by Dr. Rohatzsch.

EXTEMPORANEOUS VESICANT.

By DR. BARCQ.

INTO a flat glass, pour from 8 to 10 drops of very concentrated ammonia; cover the liquid with a large piece of linen on a rather less diameter than that of the glass, and slowly apply this little apparatus to the previously shaved skin. Keep the whole in its place by means of moderate pressure with the fingers.

As soon as a red ring, about 2 centimetres in breadth, is observed round the glass, it is certain that vesication is effected. Sometimes scarcely 30 seconds are necessary for obtaining this result. It remains only to remove the apparatus, to wash the part, and to tear away with a pair of nippers the epidermis, which comes off easily and in one piece.

The dressing is according to the object in view,—to the indications of the endermic method, for example.—*Bulletin de Therapeutique*; and *The Chemist*.

OBITUARY.

(From a Correspondent.)

ON DISEASES ARISING
FROM THE

DEFECTIVE EXPANSION OF THE
LUNGS IN EARLY YOUTH;

*Being the Goulstonian Lectures at the Royal
College of Physicians, delivered*

By GEORGE HILARO BARLOW, M.D.

Fellow of the College, and one of the Physicians
of Guy's Hospital.

2.—THE second class of cases, in the first division of my subject, includes those in which the defective expansion of the lungs arises from some mechanical pressure exercised either upon them or the air-passages.

Thus, a young man, aged 25, was admitted into Guy's Hospital, under the care of Dr. Bright, who had been afflicted with hump-back since his seventh year. His symptoms during the time he was in the house were urgent dyspnoea, orthopnoea, general venous congestion, and great drowsiness. He died rather suddenly, just after leaving the water-closet.

When the body was inspected, there seemed to be scarcely any neck; and the upper opening of the chest was very much contracted. There was a great projection forward of the first dorsal vertebra.

There were some ounces of water in the pericardium, and several in the right pleura. The heart was large and blunt; the right side much dilated; ventricle thick and firm, and containing a cystiform clot. The tricuspid opening wide, and the curtains of the valve unequally thickened, so as to allow reflux. The left side was rather diminished in capacity and substance, though still strong, especially the auricle (a small oblique opening existing between the auricles). The aorta was small: the pulmonary artery large, and its lining coarse.

The trachea just above its termination was flattened posteriorly on the left side against the vertebrae.

The lungs were of moderate size, and though fleshy and tough, yet crepitant throughout, and in part emphysematous; there was some pasty matter in some of the tubes.

The liver, dark, indurated, and myristicated.

The chain of causation in this and similar cases being nearly if not altogether the same as in those of the preceding class, need not detain us; the only difference being that here the origin of the mischief is to be found in the mechanical compression exercised upon the trachea by the projection of the vertebra, and perhaps in some measure by that upon the lungs, by the abnormal form of the walls of the chest; the effect, however, of this defective expansion remaining the same as in the former instance. I would, however, in passing, express my belief that such cases are comparatively rare, for on searching the ample records of our museum at Guy's Hospital I have found it difficult to meet with an unexceptionable instance.

There is, however, another source of contraction of the chest, of more common occurrence,—I mean that produced by false membrane effused in pleuritis. Now when the diminution of the cavity of the chest arising from this cause is considerable, or when the effusion of false membrane has occurred on both sides, we should expect that, the expansion of the lungs being impeded, the same train of consequences would ensue as has been described when speaking of the first class of cases.

It may, however, happen, where the contraction exists only on one side, that the opposite lung expands, and is called into compensatory activity. In such a case, the evils which have been just enumerated are avoided; but there is great danger, especially if there exist any tendency to tubercular disease, lest such disease should develop itself in the lung which is become thus over active; for, as I shall hereafter endeavour to prove, a part where functional activity is increased is more particularly liable to become the seat of tu-

bercular disease. I need hardly observe that in either case the danger must be greatly increased where the growth is not completed; and, therefore, that the effusion of false membrane on the surface of the pleura is a far more formidable evil in the growing subject than in the adult.

3. The third class, in the first division of my subject, includes a set of cases the true nature of which seems to me to have hitherto escaped the notice of pathologists; those, namely, in which the obstruction to the circulation on the right side of the heart is the result of *pericarditis acting mediately through the impediment which it offers to the respiratory movements*.

Few persons can, I think, have frequently and carefully observed the position and respiration of patients affected with pericarditis, without noticing the general difficulty with which they breathe, and especially the very great inconvenience which they appear to suffer from the descent of the diaphragm. Now, if this state of things should continue for a long time, in a person whose growth is not yet completed, it is evident that the obstruction thus opposed to the exercise of the lungs must impede their development, and thus give rise to the circulation on the right side of the heart, and its consequent evils.

The mode in which this is brought about will, I think, be made more apparent by the following case.

Jane Gompertz, aged 17, of rather short stature, became my patient at the Surrey Dispensary in June 1837. Her health, I was informed, had been good till her twelfth year. About six months afterwards she suffered from severe pain in her joints, which was followed by swelling, followed by palpitation. From her twelfth year she was very short-breathed.

When I first saw her, there were considerable livor, orthopnoea, ascites, and oedema, affecting principally the lower extremities. She passed the whole of the day and the greater part of the night leaning forwards in a chair, with her elbows resting upon a table.

June 28, 1837, I made the following note. A loud bellows sound accompanies the first stroke, and is most distinctly heard on the left of the mamma, nearly under the axilla; there is also a rough diastolic sound (a friction sound?); heart's impulse widely diffused; fulness of præcordial region; pulse 120, small; urine scanty, highly coloured, not albuminous.

She was much relieved by purgatives and diuretics, sometimes combined with mercurials and small doses of digitalis; and the bellows sound in a great measure disappeared, but could be produced by directing the patient to hold her breath for a few

seconds. She so far recovered as to be able to walk from the Borough to the upper part of Regent Street every morning, and back again in the evening, but was still short-breathed, and subject to palpitation upon exertion. I lost sight of her after her recovery, if it could be so called, till the summer of 1841, when she again became my patient at the Dispensary. She had in the interval grown somewhat in height, and become much stouter; the mammae were fully, perhaps excessively developed; menstruation had also been established, and continued regular for a considerable period.

On the 16th of Sept. 1841, she was admitted into Guy's Hospital, under the care of my colleague Dr. Addison, when her condition was thus described by his clinical clerk, Mr. J. H. Browne.

"At the present time her breath on exertion is very short; she has occasional sickness, with slight cough, and frothy mucous expectoration, and orthopnoea; she has pain in the region of the heart and about the lower region of the right scapula, in both of which places there exists a considerable protuberance, from distortion of the thoracic parietes, which has been gradually increasing. Pulse is 84, irregular, small, and rather vibratory; the chest is very resonant on percussion, and respiration seems natural on auscultation, though rather sonorous. The action of the heart is loud, quick, and irregular; a loud and long *bruit de soufflet* accompanies the first sound, and is most distinct to the left of the left mamma; the second sound is indistinctly masked by the first. The impulse of the heart is greatly augmented and diffused. There is no oedema, but some engorgement of the liver, which is evident below the ribs. She has not menstruated for nine weeks, and at that period the flow was very scanty."

She obtained temporary relief, and left the hospital. She again became my patient, and improved so far as to be able to walk a mile and a half to see me, and back again. She soon relapsed, was again slightly relieved, but upon the whole, dyspnoea, oedema, and ascites, continued to gain ground, and she died on the 21st of May, at the age of 22; ten years from the commencement of her illness, and five from the time she first became my patient.

The body was partially examined by my friend Dr. Birkett, and myself, about sixty hours after death.

The heart generally was very large; there was extensive pericardial adhesion, some of which was cellular, and evidently very old. There was a thick white deposit, with some grains of ossific nature on the anterior surface of the right auricle. The auricle itself was large, thick, and distended, as was also the right ventricle. The auriculo-

ventricular opening on the same side was rather larger than natural (it readily admitted four fingers). The valve was healthy, though, when the ventricle was distended, it could not perfectly close the orifice. The pulmonary artery was very small; the valves beautifully perfect. On the left side, the pulmonary veins were small, the auricle thick and large, but in a much less degree than the right; the auriculo-ventricular opening small. The mitral valve healthy; the curtains were, indeed, rather small in reference to the ventricle, though by no means so in reference to the orifice. The ventricle was large and thick, though by no means so much so as the right; and the columnæ carneæ were very large. The lining membrane of the heart was healthy; in that of the aorta were some small spots of atheroma.

The lungs, where cut into, were tough and fleshy; the trachea just below the larynx would barely admit the little finger of a small hand. The measurement was judged by experienced anatomists to be that of a child from eleven to twelve years of age.

The liver was large, and much myristicated. One kidney was examined, and appeared of fair size, apparently rather congested.

Upon the principles which have been already laid down, the series of causation in this case appears to have been rheumatism; pericarditis, with some adhesion; impeded motion of the ribs and diaphragm; defective development of the lungs and air-passages; obstructed circulation through the lungs and right side of the heart; obstruction to the return of the blood through the venous auricles; enlargement of the liver; general dropsy; death.

Before proceeding to notice any other hypothesis upon which to account for the origin of the disease, I may, perhaps, be allowed briefly to describe another case, somewhat more complicated indeed than the last, since there were found traces of endocardial lesion, though slight: but which affords an apt illustration of the connection between pericardial disease occurring in early youth, and defective development of the lungs and air-passages, with hypertrophy of the heart.

Mary Ann D—, when about thirteen years old, was affected with severe illness, accompanied by much pain in the left side, and urgent dyspnœa, but, as far as could be learned from the statement of her parents, without any obvious rheumatic affection. During the last three years of her life she was frequently under my care, with pain in the region of the heart, palpitation, and dyspnœa. Her growth was not materially impeded, and her figure was well formed;

excepting that the chest was rather small, and the spine curved backwards, so as to render her what is commonly called round-shouldered, but not to such a degree as to constitute a deformity. During the aggravations of the dyspnœa and palpitation, for which she became my patient, her legs were generally oedematous; and latterly there was much ascites, with evident enlargement of the liver. During the last three months of her life a harsh systolic murmur was observed over the situation of the base of the heart. The mammae were moderately developed, but she had never menstruated.

Sec tio cadaveris 48 hours after death.

The body was far advanced in decomposition, and we were allowed to make but a very hasty examination. There was universal adhesion of the pericardium, in parts by cellular, and in parts by more recent adventitious membrane: the oldest adhesions were situated posteriorly, and near the apex of the heart. The left auricle was large and thick: there was some sub-membranous deposit near and around the edge of the mitral orifice. The orifice itself was small: the curtains of the mitral valve slightly thickened and contracted. The columnæ carneæ were large, and the ventricle was capacious, its walls rather thick. The aortic orifice was narrow, and the valves pouched, as if too large for the opening: the aorta small, but its lining membrane healthy. The right auricle and ventricle were very large and thick; the latter much exceeding the left ventricle, both in size and capacity: the lining membrane and valves on the right side were healthy. The lungs were much congested, and some patches of pulmonary apoplexy were observed. The left bronchus was much compressed. The trachea was very small, being equal in size to that of a child of eleven or twelve years old. Liver much myristicated: much effusion into the peritoneal cavity, the membrane opaque. Kidneys healthy.

Now I am aware that it may be said—indeed I know that it has been said—that the hypertrophy of the heart is the immediate and necessary consequence of the pericardial adhesion, owing to the impediment afforded by the latter to the action of the heart. But, in the first place, it appears to me that such an assumption is altogether gratuitous; and further, that all analogy is opposed to the belief, that the impeding the action of a muscle by any mechanical restraint induces hypertrophy of that muscle; whereas we might find many instances in favour of the opinion that it is followed by the very opposite result. Indeed, I should *à priori* be as little disposed to anticipate hypertrophy in a heart contracted by peri-

cardial adhesions, as I should be to expect excessive development of the muscles of the leg and foot of a Chinese lady; and I may take occasion to shew that a heart so circumstanced is more in the predicament of such a foot than is commonly supposed; and secondly, that we have direct proof that extensive pericardial adhesions may exist, particularly where they have resulted from pericarditis occurring after the adult age, without producing any hypertrophy of the heart whatever.

[The lecturer here exhibited a complete ring of ossified pericardium which had surrounded the base of the heart in a patient of his, who had been the subject of rheumatic pericarditis twenty years before his death, and where the ossific deposit had taken place in the false membrane which formed the medium of adhesion between the two surfaces of the pericardium. The heart in this instance was not larger than natural, thus affording direct proof that adherent pericardium does not necessarily give rise to hypertrophy.]

So that, if the reasoning by which it has been endeavoured to shew that consequences similar to those observed in the two last cases will result from defective expansion of the lungs be correct; and if, too, as is, I think, evident, there is impeded respiration in persons affected with pericarditis, or adherent pericardium, we have here not only a *vera causa*, but also one capable of producing the effects assigned to it. Whereas, if we assume the adhesion of the pericardium as the direct or immediate cause of the hypertrophy of the heart, we shall indeed assign as a cause a fact of the existence of which there can be no doubt, but one which has been shewn to be inadequate to produce the effects ascribed to it.

In connection with the subject of the consequences of pericarditis upon the circulation in young persons, I may here mention another effect which, although it does not strictly belong to the class of cases which we are now considering, I am unwilling to pass over, as it affords a striking illustration of the effects of that disease in the young subject:—I mean, the arrest of the growth of the heart, and its consequent inability to maintain the circulation.

Thus, I recollect a young woman being admitted into Guy's Hospital a good deal emaciated, with very feeble pulse, and sloughing at the tip of the nose and extremities of some of the fingers and toes, she continued to lose strength, and was removed by her friends from the hospital. She died a few weeks afterwards, and I had an opportunity of examining the body. The lungs were free from tubercles, but there were extensive pleuritic adhesions, the pericardium also was universally adherent, and the heart, aorta,

and orifices of the heart remarkably small, shewing that the adhesion of the pericardium is far from causing hypertrophy, but the opposite effect, as it prevented the growth of the heart and rendered it unable to maintain the circulation.

ON

DIFFERENT FORMS OF GRANULAR DISEASE OF THE KIDNEY.

By J. D. HEATON, M.D.

[Continued from page 715.]

(For the London Medical Gazette.)

MARY CHAPPEL, age 48, admitted April 28, 1841, under Dr. Thomson, unmarried, middle stature, sallow complexion. Has been in service as a cook in a private family; of temperate habits.

Two years ago she had a fall, and struck herself severely in the left lumbar region. Since then, she has never enjoyed good health. Last August, she was affected with ascites; she was admitted into the Middlesex Hospital, and in six weeks discharged, cured of the dropsy. In less than a fortnight, however, she says, she was attacked with inflammation of the liver, and again became dropsical. The liver complaint was subdued under medical treatment, and the dropsy reduced, but her body still remained large. Since then she has been following her usual employment, but has not been in good health; she has suffered from debility, pain shooting down the thighs, and a sensation of bearing down. There has been no menstrual discharge for ten years.

Of late, the amount of fluid in the abdomen has increased so much that she has been quite unable to walk about or attend to her employment. At the time of her admission, the abdomen is much distended, and presents distinct fluctuation; but there is no oedema of the legs or other parts. She has not much pain, except an uneasy sensation of bearing down, and pain shooting down the thighs; there is slight tenderness of the abdomen. The tongue is furred; appetite poor; bowels costive; stools pale. She is subject to headache. She is free from cough or dyspnoea. Sometimes has attacks of palpitation, not violent, nor very frequent. No physical signs of disease connected with the lungs or heart. Pulse of moderate frequency; feeble, rather sharp. Urine very scanty, not amounting to more than half a pint in the 24 hours; clear, but high coloured. Unfortunately its chemical properties were not examined.

R. Elaterii, gr. j.; Ext. Gentian. ʒss.

M. ft. pil. xj. sumatur j. omni 6ta hora.

R. Ferri Potas. Tinct. gr. v.; Liqueur.

Potas. n^{xx}; Infus. Columbae, ℥iss.
M. ft. haust inter sing. dos. mist. su-
mendus.

By the 30th, the effect of these remedies had shown itself by considerably reducing the amount of fluid in the abdomen.

It was now ascertained that there was a large tumor in the left iliac, extending into the hypogastric region; it was distinctly felt to have a lobulated form, and to possess considerable firmness; it was painful when pressed. The next day, there was so much pain in the situation of this tumor, as to require the application of 10 leeches, which gave much relief.

It is unnecessary to go through the history of this case, which is rather long, and presents little variation. The treatment was principally directed to promote the action of the liver, and to remove the fluid in the abdomen by various purgatives of an hydragogue character. The urine throughout was very scanty, but, unfortunately, was not made the subject of any particular examination. Her health was rather improved for some time, and she was able to sit up, and take a little exercise in the ward. For some weeks before her death, however, she became more dropsical, and was confined to her bed by great debility. There was not, at any time, any dropsy of the cellular tissue of the legs or other parts. The urine became still more reduced in quantity; the skin was hot and dry; tongue dark brown, and adhesive.

On the 21st of June, the abdomen was fully distended with fluid, painful, and extremely tender. The face was now pale and contracted, having a cadaveric expression. Respiration gasping. Tongue brown and quite dry. Teeth covered with black sordes. Pulse feeble, and very frequent. Bowels confined. Urine quite suppressed. During the night vomiting supervened; she died the next morning, remaining sensible to the last.

Inspectio cadaveris, post mortem horas 38.

The body much emaciated; abdomen distended and fluctuating; no dropsy of the cellular tissue. The uterus much prolapsed, which was not known previously; a reducible femoral hernia existed on the left side, which she had mentioned during life, and for which she had worn a truss for some time.

Thorax.—A small quantity of serum in the right cavity of the pleura. A few old inflammatory adhesions between the two layers of the pleura posteriorly on each side. The surfaces of the pleura on each side extensively covered with recent lymph of a bad character, being soft, semi-opaque, and apparently incapable of perfect organization; in some parts granulated; in others spread evenly over the surface. The lungs were not much diseased; a few miliary granulations were scattered through each in small groups.

Near the apex of the right lung was a small dense mass, around which the surface was puckered and irregular. In different parts, lying superficially under the serous membrane, were small masses of craccaceous matter, rather smaller than a pea. The heart was rather pale and flabby, but appeared free from disease. It weighed 9 oz. 2 dr.

Abdomen.—The peritoneal sac contained a large quantity of clear yellow serum. When the contents of the abdomen were fully exposed, the intestines were observed to be pushed upwards, and to the right side, by a large tumor occupying the left iliac region, extending inwards to the median line, and upwards of an inch above the umbilicus.

It was free anteriorly and laterally; posteriorly, it was attached to the uterus, rectum, small intestines, and posterior walls of the abdomen. The tumor was larger than a man's head; when separated, it weighed 7 pounds 3 ounces. It was evidently a multilocular cystic degeneration of the left ovary. It consisted of innumerable cysts of every variety of size, from that of a large orange down to that of a mustard seed. The larger ones had thickened opaque walls, in which were formed numerous smaller cysts; they contained a curdy-grey fluid of a very bad smell, amongst which were films of an opaque white substance, having a somewhat iridescent lustre, and presenting much the appearance of boiled fish-skin. The smaller cysts were semi-transparent, and contained a clear serum*. The intestines had a dark, greenish colour, but without much appearance of vascularity.

The peritoneum was thickened and opaque. The whole of the surface was studded with granulations, varying in size and number in different parts: on the mesentery, they were small and very numerous; over the liver, and on the tumor, they were larger and more irregularly scattered. They were mostly semi-transparent, of a rather firm consistence, and could be removed from the serous membrane without causing any laceration of its surface. Some of them were globular, and attached by a short stalk. Over the liver were some shreds of soft, opaque lymph, which, when held up to the light, presented numerous granules in their substance. The liver was small; it had a pale colour, but, further than this, presented no morbid appearance.

Kidneys.—The right kidney was small; it had a faded, yellowish grey colour, and felt very soft and flabby. In removing the capsule, the cortical structure was so soft and adherent as to tear off with it in irregular patches. The surface was irregular and coarsely granulated. On laying it open, the same colour and diminution of cohesion were found to pervade both the cortical and

* A model of the ovarian tumor is preserved in the museum of University College.

tubular part. The apices of the papillæ had more redness, and appeared less diseased, than the rest of the tubular structure. No red points, nor other traces of vascularity, were perceptible. This kidney weighed $3\frac{1}{2}$ oz. The left kidney was also granulated; it was larger, and still softer than the right, so that it was impossible to separate the capsule without removing a large portion of the cortical structure along with it. It was much elongated, and had a more irregular surface than the right kidney, but its internal surface was very similar. It weighed $4\frac{1}{2}$ oz. The uterus was of the natural size when not impregnated. It did not appear itself diseased; but there was a morbid structure formed in the cellular tissue between this and the rectum, consisting of irregular masses of a cartilaginous hardness, semi-transparent, and of a greyish colour. Amongst these masses was a small cyst of the size of a filbert, containing a brown matter of a smooth, pasty consistence, and having a faint, feculent odour. It had no communication with the rectum, which, as well as the cyst, seemed quite entire.

No morbid appearances were discovered in the brain.

The above report is deficient in some observations which it would have been desirable to make during the progress of the disease. Had the post-mortem examination not taken place, the disease of the kidneys would not have been suspected. It seems not improbable, however, that this disease originated with the blow on the loins two years ago. The dropsy was confined to the sac of the peritoneum, and it is the absence of any cellular effusion (which is so usual a symptom in connection with albuminous urine), to which must be attributed the neglect of an examination of the urine and the state of the kidneys during life. No mention is made, in the previous history of the case, of this kind of dropsy having existed at any former period, nor of any other symptom distinctly referrible to the kidneys. This is remarkable, as dropsy is one of the symptoms the most frequently present, of those not *essential* to the disease; and where dropsy does exist in connection with granular degeneration of the kidneys, it is almost invariably anasarca affecting the limbs and face; the effusion into the serous sacs either occurring only at a very late period in the disease, or being dependent on some organic disease of other organs. As, in this case, the diseased state of the peritoneum itself is sufficient to explain the effusion from its surface, it appears probable that this effusion might not be, in any degree, due to the coexisting disease of the kidneys, and that this was one of those more uncommon instances where these organs proceed to an advanced stage

of degeneration, without producing the symptom of dropsy—cases which, though rare, do sometimes present themselves. Allowing the ascites to be independent of the disease of the kidneys, it seems not impossible that it acted derivatively, and served to prevent the dropsy of the extremities.

The ascites seemed to have depended on the tubercular inflammation of the peritoneum. The liver presented no such appearance of disease as to lead to any certain opinion that the dropsy depended on obstruction to the circulation through this organ. The peritoneal inflammation presented all the gradations between shreds of bad lymph and the rounded tubercles of a still lower organization; some in the state of cartilaginous hardness and transparency, analogous to miliary granulations; and others passing into the opaque and softer state of *crude* tubercle. All were rounded and prominent, for the accompanying ascites had borne off the pressure of adjacent parts which might otherwise have flattened them. The serum was quite transparent, having none of the opacity and semi-purulent appearance common in the effusions of tubercular inflammation.

The appearance of the kidneys differed considerably from that described in most of the preceding cases; this difference consisting principally in the great softness and fragility of their substance; whereas, induration, though frequently combined with friability, is the more usual condition where the kidney has assumed a distinctly granular appearance, and already undergone some contraction. The disease appeared to invade extensively the tubular as well as the cortical structure, and no doubt the function of the kidneys must have been much interfered with. For the last two days of the patient's existence no urine was excreted from the bladder, and the discharge had been very scanty for some time. There was, however, none of the oppression of the faculties, and gradually invading coma, which usually presents itself where suppression of urine accompanies the fatal event.

The disease of the ovary presented the usual appearances of multilocular ovarian tumor. The pellicles spoken of as contained in some of the cysts, were analysed, and found to consist principally of cholesterine.

The morbid growth between the uterus and rectum appeared to be of the nature of scirrhus. It was remarkable that it should have become so extensive without producing more marked symptoms during life than an uneasy sensation of bearing down, the only one of which the patient complained having reference to this morbid appearance. It is singular, also, that, situated so near to, and even in contact with the uterus, an organ

so prone to disease of this nature, it should still have remained free from contagion. The pasty substance contained within the cyst much resembled fecal matter, and may perhaps have escaped from the rectum through a perforation the result of ulceration or other injury, where the absence of peritoneum obviated the danger of serious peritonitis, but where, having no means of escape, it had become inclosed in a membranous cyst; and it is possible that the irritation caused by this foreign body may have been the original cause of the morbid structure by which it was surrounded.

The recent inflammation of the pleura was of that sub-acute character which I have, in previous cases, remarked to occur frequently in the last stage preceeding death, in connection with granular degeneration of the kidneys.

CONTRIBUTIONS

TO

ANATOMY AND PHYSIOLOGY.

By ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

[Continued from page 720.]

ON THE CORPUS LUTEUM.

No. 7.—*Uterus precisely similar.*

RIGHT ovary small. No corpus luteum externally. Numerous Graafian vesicles, some of considerable size. The ovary being cut directly across about its middle, two minute yellow bodies may be seen near that portion of the ovary where the corpora lutea are usually placed.

Left ovary. Abundance of Graafian vesicles. One large corpus luteum, and a smaller, equalling the one just described; it presents a tolerably distinct central cavity, although there was no appearance of a hole on the surface: each of these corpora lutea measures in diameter about four lines. The most projecting part of the largest presents no opening; and on slicing with great care we find no canal or cavity in the interior. The other corpus luteum (smaller) is still large on cutting into it.

No. 8.—*Uterus and Ovaria in every respect similar to the preceeding.*

We have already remarked, that it was admitted that some of these twelve gimmers whose uteri had been

sent us might be gravid: upon a superficial view of the whole, three of them were so evidently larger, and to the touch so clearly seemed to contain some foreign body, that they were examined separately and last, and gave the following results:—

No. 9.—Uterus weighs 12 oz.; length from os uteri to fundus, 5 inches 6 lines; weight of fœtus in right horn, 60 grains; weight of fœtus in left horn, 40 grains.

Dissection.

Upon opening up this uterus a fœtus was found in each horn, whose weight we have prefixed.

Ovaria present a corpus luteum in each.

Right ovary presents upon its surface the usual appearance of Graafian vesicles (?). And on a vertical incision being made of the whole organ, the same vascularity appears as has been noted in the preceeding cases in reference to the corpus luteum. The whole ovary is more vascular than in any of the unimpregnated ones. There is an appearance of a central cavity, but no opening or short canal leading to it. Here, as in several other ovaria, on examining the external surface of the vesicles (Graafian?), which adjoin the corpora lutea, it is easy to see a great vascularity upon the surface of these vessels whilst distended with their contained fluid, and there is one now before us (about two lines in diameter), the exterior surface of which, and closely adjoining the corpus luteum just described, is exceedingly vascular, but otherwise has no connection whatever with the corpus luteum, except its close proximity.

Left ovary resembles the right one.

No. 10.—*Uterus contains a lamb in each horn, and bears the strongest possible resemblance to No. 9.*

Right ovary large. Corpus luteum fully formed in the usual situation, but no opening apparent on the surface, the peritoneum seemingly passing uninterruptedly over it. On being divided in the manner that the bodies are usually bisected (*i.e.* from pole to pole), no central cavity is visible, nor any canal, and it presents appearances precisely similar to No. 8, although the effusion of blood is not so great.

The left ovarium has its corpus

luteum precisely like the preceding. No orifice is found leading to any central cavity, and on making numerous horizontal slices of this corpus luteum quite to the base, we can observe not the slightest appearance of a cavity.

Both these corpora lutea were very firm, the peritoneal tunics being stretched as it were over them, as by their presence; they were also vascular.

No. 11.—*Uterus similar in dimensions to the last (No. 10.) The horns are enlarged, and have evidently a fetus in each side.*

Both ovaria appear entirely composed as it were, of one corpus luteum in each. I examined them with great care, and by dissecting them fairly out of the ovary almost satisfied myself that they were glandular bodies. With care they can be dissected quite entire; more especially, if left covered with a delicate cellular texture, which covers and invests them precisely as the similar texture does the fetal kidneys, thymus gland, &c.

No. 12.—*Uterus, gravid, contains two lambs, and in all respects resembles the preceding.*

No. 12.—In my note-book I find the following observation, 15th September. The ovaria of a ewe are now before me. This animal had had three lambs at different times; the last in the spring preceding the autumn in which it was slaughtered. The vesicles of De Graaf are numerous and obvious, but there is not a vestige of a corpus luteum.

No. 14.—*Sheep's uterus.*

Gimmer, æt. 2. Never had lamb. Presents precisely the appearance of those examined previously.

Ovary (right) weighs 16 grs. Numerous, but rather small, Graafian vesicles. No distinct yellow body. I have, with the utmost care, dissected out a Graafian vesicle, entire, from the stroma: this requires dissection, in consequence of the numerous vessels which pass towards it. Externally, the cyst presents still a flocculent aspect, as if covered irregularly with cellular membrane, and especially cut blood-vessels. I opened this cyst with delicate sections, and found the interior occupied with a limpid colourless fluid, and, floating in the interior, a granular looking membrane collapsed, and here and there torn across; it floated readily

out of the cyst, and with a minute, white, opaque body. The cyst left still with the ovary is smooth internally, with numerous blood-vessels distinctly seen ramifying in its walls. Unless the opaque body is the ovule, which I have unfortunately cut into in opening the cyst, I can see no other body to answer for it.

Ovary (left) weighs 28 grs. Presents a well-marked yellow body, though not vascular, and, if my theory is correct, receding or going back. There are eight distinct Graafian vesicles, though these are small in size. I proceeded to dissect in the line of the entrance of the vessels (*i. e.* posterior or fixed margin), and came upon a very distinct and beautiful Graafian vesicle. It is spherical, delicate yellow, like, in fact, the ova matured of a trout; a large blood-vessel distributes its branches to it. It is placed close to the corpus luteum, which itself feels at its base soft and pulpy, as if a fluid were in the centre. I have opened this beautiful cyst with the greatest care, and find its contents precisely similar to that described in the other ovary, *i. e.* a fluid with a collapsed membrane (granular looking) inside. The latter floats out with the fluid, which is limpid and clear. The vascularity of the cyst is perfectly beautiful. The inner sac appears to have no direct communication with the cyst.

The yellow body was remarkable for its yellow colour, and want of vascularity. There is assuredly no cavity in the interior, the arrangement being strictly that of the cow.

No. 15.—*Uterus of a Quey.*

Weight, 10 oz. Length, from os uteri to fundus (bifurcation), between the horns, 9 inches.

This animal was stated by the butcher to have been about two years old, and most assuredly never to have had a calf.

Left ovary weighs 52 grs. Length between poles, 1 inch, 2 lines; diameter across, 6 lines.

Externally, this ovary presents numerous semi-transparent spots, which are evidently cysts full of a fluid. At one point I observe a small puckered orifice (like the natural opening of an abscess). The whole ovary feels as if filled with a fluid. No prominent yellow body, as is seen so well marked

in the other ovarium. In order to vary the sections, I cut along the posterior (fixed margin of the ovarium), and found the interior nearly occupied with a cyst full of a yellowish serous fluid. The cyst also contained flocculi, as of portions of a delicate membrane broken up. The cyst itself consists of a firm almost semi-cartilaginous membrane, on which I observe ramifying numerous blood-vessels carrying red blood. I can readily insulate the cyst from the surrounding stroma. The interior appears perfectly smooth. The knife has bisected one of these irregular looking vermilion-coloured patches, placed close to the cyst, but, so far as I can trace, having no immediate connection with it. The vermilion colour of this patch evidently does not depend on the presence of blood, but it looks more like a piece of dyed silk velvet. There seem to be six or seven of these vermilion-coloured patches, varying in size; and I can distinctly feel that the ovarium has a greater degree of density and solidity in those parts. I observe, above, the existence of a small puckered orifice; it is placed in the centre of a yellowish spot, has no connection with the cyst, but seems to me to be the remains of one of those yellow bodies (*corpora lutea*) seen in the sheep and cow, and which are originally the vermilion bodies.

There is another pretty large cyst in this ovarium, and numerous smaller ones, all containing a yellowish fluid.

Right ovarium, pole to pole, length, 1 inch, 3 lines; from uterine pole to apex of corpus luteum, 1 inch, 6 lines; diameter across, 1 inch; weight, 146 grs.

Externally the ovarium is studded over with prominent vesicles (there are at least twelve of these, all full of a fluid), projecting from the free margin, and looking outwards. There is a prominent vascular yellowish body, the apex presenting distinctly the same puckered-like appearance as described and drawn by me in the sheep. A transverse section of this body, four lines from the free extremity, presents a fine close but glandular looking structure. Nearly central, I see distinctly a change of structure, appearing to me to be condensed cellular membrane; as if it were the fine cellular texture which surrounds and invests the body itself, was here collected and

puckered up. A second careful inspection shews it to be distinctly connected with numerous white cellular bands running towards the surface, and to be rather of an elongated form, like a cicatrix.

Weight of this body, 86 grs.; total weight of ovarium, 146 grs.; weight of ovarium, 60 grs.

The above weight was taken after I had dissected it carefully out of the ovarium: this is readily done, its connection being only cellular, and no doubt vascular, although I observed no very considerable vessels, or pencil of vessels, divided; it is still invested with a fine cellular membrane. The prominent part seems to me completely invested by the peritoneum and a thin layer of the proper ovarian tunic. If the investing cellular membrane, on the other hand, has not given way, it is unquestionably extremely thin on this projecting part. On a re-examination of this body and ovarium this morning, I am almost satisfied that it is originally one of these vermilion bodies (glandular), goes on to development, performs some function (why not a fluid connected with the passage? a preparatory stage to the passage of the vesicle itself? a purely secreting organ, and not analogous to the corpus luteum in man?) The body then wastes away, loses its vascularity, becomes yellow, and presents the appearance of a small puckered hole, surrounded with a dense base, precisely like the healing of an abscess. It appears altogether so.

No. 16.—*Uterus and ovaria of a cow said never to have had a calf.*

Weight, 12 oz.; length from os uteri to fundus, 7 inches, 6 lines.

The interior of this uterus is of a yellowish skin colour, and with no appearance of vascularity anywhere. The cotyledons are distinct, though in no shape vascular, and present the appearance of little mammillæ cut longitudinally.

Right ovarium weighs 31 grs.; length from pole to pole, 10 lines; is nearly globular; not unusually vascular; smooth externally; and near its distal pole has two spots on its surface: these are about one line in diameter, having a puckered straw-coloured edge or disk, with a bright red centre. The remainder of the ovarium seems nearly

entirely composed of two large vesicles: one of these is larger than the other; and at one part the tunics seem extremely thin, semi-transparent, as if distended and ready to give way by the pressure from the contained fluid. I succeed, with the point of a fine lancet, in dividing the peritoneal envelope, and separate it, to the extent of more than a line, from off surface of the largest vesicle; but this now gave way; a quantity of perfectly limpid colourless fluid escaped. The inner surface of the vesicle showed great vascularity, but I could observe no *membrana granulosa*. In examining one of the smaller vesicles, I have been a little more fortunate in finding, in the interior, shreds of what seemed to have been the *membrana granulosa*; but I can perceive nothing like the *cumulus* or disk with the ovum. In dissecting this ovarium, I observe the texture of the body itself feels and cuts like a piece of cartilage, particularly around the spots I have already alluded to, which, by the bye, I find pass deep, retaining their brick-dust colour, into the centre of the ovarium.

Left ovarium weighs 100 grs.; length from pole to pole, 1 inch, 3 lines.

This ovarium has an oval compressed form, and its distal extremity, or that looking towards the fimbriated opening, is nearly entirely occupied with a glandular looking body; numerous vessels carrying red blood are seen on the surface, more particularly towards a projecting part of the body, at the blunt apex of which I observe a depression, if not a hole, leading towards the interior. (I have just assured myself that the peritoneum, at least, passes over this apparent hole in the yellow body.) Near the internal pole I see four spots precisely similar to those described on the right ovarium, and at least three distinct vesicles; the diameter of the largest is three lines. A two-inch microscope shews me numerous smaller vesicles. I have dissected out one of these vesicles very readily, and find, in the interior, shreds of a membrane with abundance of fluid. Near the vesicle lies a rounded body, the size of a pea, of a dark blue colour; upon making a section of it, I find its contents fluid blood. The inclosing membrane was extremely thin, but strong.

No. 17.—*Uterus of a cow said to have had two calves.*

Weight, 16 oz.; length from os uteri to fundus, 10 inches, 6 lines.

The os uteri in this specimen presents numerous deep fissures; it has a more cartilaginous feel under the knife. The parietes of the neck and horns are thicker, presenting numerous large vessels cut across. The inner surface has a darker, more fleshy, colour. The cotyledons project, and want that central fissure remarked on the virgin cotyledons (No. 16). The broad ligaments present numerous very tortuous vessels running between its folds.

Additional facts wanted.

1. Age of the cow.
2. When she last had a calf.
3. At what particular period does the cow receive the male.
4. How long will she suckle the calf.

Right ovarium weighs 140 grs.; length from pole to pole, 1 inch, 2 lines.

It seems nearly composed of a reddish glandular looking mass, on the surface of which numerous blood-vessels may be seen ramifying. These vessels appear to me peculiar: they are not like the branches of a larger trunk, but appear like short, rather irregular-shaped, canals; and the microscope shews innumerable fine vessels (containing red blood, however) connected with these, and communicating everywhere with each other. Are these, then, the capillaries of the ovarian arteries, or are they new vessels? Is it this appearance which has induced some persons to compare the function of the ovaria to a sort of inflammation? The vessels are certainly precisely like those which I once saw in a pseudo membrane, in a case of pericarditis.

The ovarium presents no very distinct specimens of peculiar reddish spots, so well marked on the virgin ovarium (No. 16); but, 1st, the large glandular looking body already alluded to; 2d, another glandular looking body, of a yellowish colour, much smaller than the first, and with a very distinct hole and depression in its most prominent part; 3d, semi-transparent vesicles, three distinct and pretty large: these appear to me double, *i. e.* either composed of *two* vesicles, or *one*, having something like an opaque line running down the centre.

Left ovarium weighs 85 grs.; length of fixed margin or base (pole to pole), 1 inch, 2 lines.

This ovarium seems nearly entirely composed of vesicles, two of them large, having a diameter of nearly six lines; blood-vessels are seen ramifying on the surface. There are, in addition, numerous opaque spots, like small vesicles; but above all I observe two very distinct fissures about a line in length. The edge of these fissures feels, under a delicate probe, indurated, semi-cartilaginous; a section made into the ovarium, near one of them, shews that it is in immediate connection with a small yellow body: this, then, I conceive to be the remains of a large reddish yellow body, such as we have in the other ovarium; and, indeed, the second observation in the preceding description of the right ovarium appears to me really one of these bodies gradually losing its formation (whatever that may be), and disappearing, ultimately to assume the appearance of a depressed fissure with indurated edges, as is seen in the ovarium now under consideration.

No. 18.—*Uterus of a cow, said to have had four calves.*

Weight, 27 oz.; length from os uteri to fundus, 11 inches.

The os uteri here presents the fissure I have alluded to in No. 17, still more developed, giving rise, in front, to numerous lobulated folds. The neck, body, and horns, but still more like a cartilage; and the section displays still more distinctly innumerable vessels cut across, and, as it appears to me, contracted, not carrying fluid even during the life of the animal. The cotyledons now look like large irregular elevations, the section shewing a greater number and a more minute condition of, blood-vessels.

Additional facts wanted.

1. Age of the cow.
2. When she last had a calf.

Right ovarium weighs 145 grs.; length from pole to pole, 1 inch, 2 lines.

This ovarium seems to me curiously placed in respect to the poles and fimbriated extremity of the uterine tube: this is probably caused by the adhesions of the peritoneal laminae of the broad ligament. It is elongated, kidney shaped, presents numerous large

distended vesicles, with fine (not very well defined) brick-dust coloured spots irregularly dispersed over the surface. One of these appears to form a part of the wall of a vesicle.

Left ovarium weighs 205 grs.; length from pole to pole, 1 inch, 2 lines.

This ovarium presents a large reddish-yellow, glandular looking mass—it wants symmetry;—numerous red spots; and, what I have not hitherto observed, numerous white granular looking masses, slightly elevated on the surface. The fimbriated margin has a remarkable fleshy appearance. Numerous thin transverse stripes of the yellow body displayed nothing like a central cavity. I observe that immersion in proof spirits extracts the colour from the yellow body, whilst it appears to render the red spots brighter.

No. 19.—*Uterus of a cow with calf.*

Weight of uterus, 6½ lbs.; length from os uteri to fundus, 10 inches.

The calf lies in the right horn, which projects very considerably beyond the fundus of the uterus. The fœtus, when removed from the uterus, weighs 1 lb. 4 oz.

Right ovarium.—There is a distinct corpus luteum: its external surface is very vascular, the whole ovarium being of a deep brick-dust colour. We can observe no external orifice of the corpus luteum; it seems entirely invested by the peritoneum. A thin horizontal slice being taken off from the more prominent part of the corpus luteum, blood flowed at every pore, so as to entirely cover the cut surface.

We can observe no central cavity. With the exception of its vascularity, then, it resembles the corpora lutea formerly described. A deeper slice gives the same appearance, even though such sections were continued to the basis of the body. There are Graafian vesicles in this ovary, but no other appearance of corpora lutea.

Left ovarium is small, flat, triangular, of a pale dirty white colour. Graafian vesicles numerous, but no corpora lutea. Various sections exhibit no appearance whatever of yellow bodies or corpora lutea; and the want of vascularity is quite striking.

CASE OF
PHLEGMONOUS ERYSIPELAS
TREATED BY
ACETATE OF LEAD AND OPIUM.

To the Editor of the Medical Gazette.

SIR,

THE conflicting opinions of medical men regarding the local treatment of phlegmonous erysipelas, and the implicit confidence of many in the practice of large and small incisions, which cannot at all times be made available (especially when it attacks the face), have induced me to beg that you will, through your valuable journal, give publicity to the following case, treated locally by fomentations and poultices containing acetate of lead and opium. I am not aware that the above remedies are either generally employed or sufficiently appreciated in the treatment of this disease.

I know, indeed, that the acetate of lead is considered by some a dangerous remedy when used externally, as well as when employed internally—nay, it has been considered by many a very powerful irritant poison; but I am not aware of a single fatal case from the remedy in question; yet I do not deny the fact that colic, griping, vomiting, and even palsy, may be produced by its long continued and injudicious use. These results, however, are too rare on the one hand, and its beneficial effects, in the hands of scientific men, too numerous on the other, to leave a doubt upon the mind regarding its efficacy in many affections. It exerts a remarkable sedative effect upon the nervous system; and in no circumstance is this action more fully exemplified than in allaying the pain always present in local inflammations, more especially when combined with opium. These, together, seem to act specifically in relieving the turgid and congested state of the capillary vessels common in all local inflammations; and are not only applicable to phlegmonous, but erythematous and other erysipelatous inflammations.

Opium, I am aware, has also been objected to as a local remedy in erysipelas, from the misconceived idea that it repels the eruption; an idea probably founded on the fact that inflammatory action has frequently been suddenly

arrested under its use. But what are the indications? Are they not to allay pain, and arrest the inflammatory action? And I know of no local remedy more efficacious in fulfilling these indications, and in preventing gangrene and sloughing in erysipelas, than the acetate of lead and opium, employed as above described. I do not make these assertions from a crude or indigested theory, but from a careful observation of facts; and I should not consider myself in the discharge of an important duty, which every medical man owes to the profession and the community, if I buried in oblivion that which considerable experience has taught me is not only efficacious but safe.

I have often reflected with admiration on the character of Sydenham, who says, "I have always thought it a greater happiness to discover a certain method of curing even the slightest disease than to accumulate the largest fortune. * * * Can a person give a stronger proof of his benevolence and wisdom than by endeavouring always to promote the public good rather than his private interest, as he makes so inconsiderable a part of the whole? And, in reality, as it is the part of a wicked man to destroy his fellow creatures, so it is the duty of a good man to preserve them, and instruct others how to preserve them, from death."

If, therefore, the foregoing and following remarks shall in any way benefit my professional brethren, and, through them, be made applicable and efficacious in the relief of suffering humanity, I shall consider myself not without reward.—I am, sir,

Your obedient servant,

WILLIAM SMITH, M.D.

Weymouth, February 16, 1844.

CASE.—Master R. B., *æt.* 4½ years, has just recovered from scarlatina; is one of a family every child of which exhibits evident signs of struma; was attacked with erysipelas of the face and scalp on Tuesday, January 9th, of the present year, and was placed under my care on the Friday following. When I first saw him, the right side of the face, embracing the forehead, right eye, cheek, and right side of the nose, was very much swollen. The erysipelatous blush was confined to a portion of the scalp, forehead, right eyelid, and side of the nose, on which surface numerous

minute vesicles appeared, and were filled with a limpid fluid. There was much general excitement and fever present; pulse 138 beats per minute; the tongue foul and dry, with much thirst.

R Hydrarg. c. Cretâ, gr. iij.; Pulv. Rhei, gr. vj. M. ft. tales vj. One to be taken every two hours.

R Acet. Plumb. ʒj.; Pulv. Opii, gr. x.* Misce pro lotione. To be dissolved in twelve ounces of hot water, and applied to the inflamed surface, through means of soft cloths, kept constantly wet.

13th.—Patient very restless, and has been so during the night; four powders taken; bowels have not acted; skin hot and dry; pulse 132; tongue covered with a yellow fur. Powders omitted.

R Tinct. Sennæ, ʒij.; Infus. Sennæ, ʒij.; Sulph. Magnes. ʒss.; Tart. Antim. gr. iss.; Syrupi Simp. ʒj. M. A dessert spoonful every half hour, until the bowels are freely opened. Lotion continued.

Saw him again in the evening, when it was reported that he had slight vomiting after taking the third dose of the above mixture, but not afterwards, though it was regularly administered. Has had a very scanty dark coloured stool.

Medicine to be continued, and hair removed.

14th.—Passed a very restless night; medicine all taken; no further motion of bowels; tongue much loaded; pulse 136. The minute vesicles have now assumed the form of broad phlyctenæ, filled with a viscid serum; the parts between them present a black red appearance. The right eyelid, on which there is a large vesicle, has a peculiar gangrenous tint. I opened all the phlyctenæ with the scalpel, and pressed out their contents, a sort of half gelatinous serum. The inflammation now extends as far backwards as the lambdoidal suture on the right side. Ordered—

A poultice of bread and water, containing half a drachm of the acetate of lead and ten grains of opium, to be applied to the whole of the inflamed surface.

* For adults I may remark that the quantity of opium ought to be increased to half the quantity of the acetate of lead, or even more; but as decomposition takes place, the acetate of morphia being formed and held in solution, while the meconate of lead is precipitated, it is better to have an excess of the acetate of lead over the opium employed. The solution ought to be strained through fine linen before being used.

R Calomelanos, gr. iij.; Pulv. Rhei, Carb. Sodæ, aa. gr. iv. M. ft. tales ij. One to be taken immediately, and the other after three hours if the bowels are not previously opened.

3 o'clock.—Saw the patient again; both powders taken; bowels not acted on. Ordered a simple enema.

Saw him again at half-past eight. The enema was administered; examined the ejected matter, and could scarcely detect any fæces in it. Pulse 140; tongue black in the centre, and parched; tip and edges a bright red colour. Ordered—

The enema to be repeated, with the addition of Tinct. Assafoet. ʒij.

I waited, and saw it administered, and, like the former, it brought away very little faecal matter.

R Infus. Sennæ, ʒij.; Sulph. Magnes. ʒvj.; Syrupi Aurant. Syrupi Simp. aa. ʒj.; Tinct. Jalapæ, ʒij. M. A table spoonful every half hour, until the bowels are freely opened. Poultice to be renewed, and to contain the same ingredients as before.

15th.—Reported to have talked incoherently, but on the whole passed a quieter night. About one-third of the mixture taken; had a copious stool this morning, very dark and consistent, and smells strongly of the assafoetida. Pulse 132, of good strength.

Mixture to be continued at intervals of two hours. Poultice to be renewed as formerly.

3 o'clock.—Has had an occasional rigor since morning; skin very hot and dry, except the extremities, which are cold; pulse 136, irregular; tongue less parched. Thirst continues, for which he has had toast-water, and a tea-spoonful of wine every two hours. The left eyelid is now much swollen. Removed the poultice, and, after placing it in hot water for some minutes, replaced it on a surface partly in a state of gangrene. Ordered the feet to be put in warm water for ten minutes, and afterwards rolled in warm flannel.

R Aq. Acet. Ammon. Mist. Camph. aa. ʒss.; Nit. Potassæ, ʒj.; Syrupi Aurant., Aq. font. aa. ʒj. M. A tea-spoonful every half hour until the one half of the mixture is taken.

9 o'clock.—Medicines regularly taken; skin rather cooler; has had a scanty stool, mixed with mucus.

Last medicine to be continued, the purga-

tive mixture to be omitted, and poultice renewed, covering both eyes.

16th.—Was delirious during the night, but slept at intervals. Pulse 132; skin moist.

Mixture continued. Poultice changed for the lotion first employed.

Spots of "*varicella vesicularis*" have now made their appearance on various parts of the body. Saw him again at 4 o'clock with my friend Mr. Trowbridge, whom I casually met. On mentioning the case to him, he very kindly accompanied me, and, after examining the little patient, considered him in a very precarious state. Pulse 140, weak, and intermitting; great prostration and stupor; skin moist.

Mixture continued. To have half an ounce of gum arabic in his drink, and wine repeated every hour.

9 o'clock.—All the mixture taken. No stool to-day. No urine passed since morning. Complains of pain in the lower bowels. Applied a cold smoothing-iron to the soles of the feet, and the effect was instantaneous: he made water to about 5xij.

Ordered the purgative mixture to be repeated, 5ss. for a dose, every two hours, until it operated freely. Warm lotion continued.

17th.—Passed a restless night; bowels opened early this morning—stool more healthy in appearance. Pulse 132, weak, slight subsultus tendinum. Tongue florid at the tip and sides; skin cooler. On removing the cloths from the affected parts I found the bases of all the phlyctenæ in a state of superficial ulceration, and many of them bled upon the slightest touch.

The right side of the head, from the lambdoidal suture forwards, embracing the temporal and frontal portions, the eyelid and side of the nose, is one continued raw surface; those parts only that were previously covered by vesicles assuming the peculiar characters of ulceration.

Ordered a simple poultice. All medicines omitted. Wine continued.

Saw him again in the evening at 9 o'clock. Has had epistaxis (a frequent symptom in erysipelas). Pulse 130, full; tongue rather cleaner. On the whole, seems better.

Renewed the poultice, with opium, &c. as before.

18th.—Passed a good night, lies quiet, and inclines to sleep. Pulse 120; tongue much improved. The varicellous eruption faded, though a few vesicles yet appear to be developing themselves. Bowels not opened.

Ordered ʒj. of the purgative mixture for a dose, and the following tonic—

R. Tinct. Rhei. Tinct. Cinchon. aa. ʒj.; Syrupi Simp. ʒij. M. A tea-spoonful thrice daily.

8 o'clock P.M.—Bowels opened; is very restless; cries much.

Renewed the poultice, with a double quantity of opium.

19th.—Passed a tolerable night. Says he is better. Pulse 120. Inflamed surface very irritable. Changed the poultice for Ung. Zinci. Has opened the left eye; right one still closed. Asked for meat this morning. Ordered sago and a little wine.

8 o'clock P.M.—Has had a remission of all the febrile symptoms. Pulse 140. Reported not to have taken the sago, but had, by desire, a little beef.

Ordered one of the powders containing calomel, &c.; to be followed up, in two hours, by a tea-spoonful of the purgative mixture. Zinc ointment continued.

20th.—Passed a very restless night. Bowels opened this morning. On examining the stool, I discovered undigested food and currants, and on more minute inquiry as to what the child had eaten the previous day besides the meat, it was reported that he had had some "bun and cheese-cake." Pulse 132.

Medicine to be repeated as yesterday.

8 o'clock P.M.—Has had two stools. Seems better.

Tonic medicine and wine continued. Powder, &c. omitted.

21st.—Slept well; pulse 120. Asked for food to-day—ordered him fish.

Continue as before.

22d.—Is still better. Pulse 112; tongue becoming clean. Says he would prefer mutton to fish—ordered chicken-broth.

Ointment and medicine continued.

23d.—Pulse 96; scalp healing rapidly; bowels open. Sat up a little this morning.

Continue.

24th.—Right cheek swollen and red,

the redness extending from the side of the nose (on which two irritable pimples appear, which he is reported to have constantly rubbed yesterday), to the angle of the jaw.

Ordered the inflamed parts to be well fomented.

8 o'clock P.M.—A second attack of erysipelas is now evident; the whole of the right cheek is a bright red colour; the right parotid and submaxillary glands are enormously swollen. The lips are so much swollen on the right as to give the mouth the appearance of being drawn to the left side. The little patient cannot open his mouth to protrude the tongue. The mucous covering of the lips presents a dark red glistening appearance.

Discontinued the lotion, and applied a poultice containing ʒss. of Acet. Plumb. and gr. viij. of opium, which was renewed twice daily, and the powders and purgative mixture administered as the circumstances of the case demanded, up to the

29th.—When the inflammatory symptoms began to subside. Precisely the same plan of treatment was followed as in the first attack, and with the happiest results. I repeat, that I know of no local application to be compared with the acetate of lead and opium in arresting the inflammatory action and tendency to gangrene in this formidable affection. The livid base of the phlyctenæ, under the use of absorbent powders, &c. &c. often terminate in gangrenous ulceration, which not unfrequently extends to the cellular tissue, forming caverns containing unhealthy pus and dead sloughs. I confess that in the above case I feared this result; but up to this time (Feb. 1st), he is progressing favourably, and has to-day, for the first time since the attack, opened his right eye; showing that the levator palpebræ and orbicularis palpebrarum are preserved from "suppuration and sloughing, and consequent disfiguration."—(Bell).

Feb. 3d.—The whole of the inflamed surface is nearly healed, and he may now be pronounced out of all danger.

P.S.—I may further add, that a poultice made of bread-crumbs, containing a drachm of the acetate of lead, and two scruples of opium, is also peculiarly efficacious in allaying the swellings of phymosis and paraphymosis, common

consequents of chancre and gonorrhœa, often known to effect gangrene and sloughing under the application of other remedies.

Never did I witness their good effects with more satisfaction than when clinical clerk at the Edinburgh Royal Infirmary. The poor patient to whom I allude had prolapsus ani, which she said was of several years' standing. On admission, the tumor appeared nearly the size of a man's clenched hand, and from the degree of strangulation it had a dark red gangrenous appearance. An attempt was made to reduce it by Mr. Symes, assistant-surgeon, and Dr. McKenzie, who happened to be in the medical wards at the time, but to no purpose. As the patient was admitted in the evening, and was entered on my list, I prescribed a poultice containing Acet. Plumbi, ʒij., Pulv. Opii, ʒss., which was kept applied till the usual hour of visit next day (12 o'clock), when the same gentlemen who had tried to replace the gut the previous day now effected its reduction with comparative ease.

ON THE EFFECTS OF OPIUM ON THE INFANT SUBJECT.

By JOHN B. BECK, M.D.

Professor of Materia Medica and Medical Jurisprudence in the College of Physicians and Surgeons of New York.

As a remedial agent opium has always and justly been looked upon as one of the most valuable in our possession. It has been styled the "*donum Dei*," the gift of God to man; and Sydenham says of it, that it is "so necessary an instrument in the hands of a skilful physician, that the art of physic would be defective and imperfect without it; and whoever is thoroughly acquainted with its virtues and the manner of using it, will perform greater things than might reasonably be expected from the use of any single medicine." High as this panegyric is, it is unquestionably just. Admirable, however, as this agent is, if properly used, it is equally true that, in unskilful hands, there is scarcely any article in the whole materia medica capable of producing a greater amount of mischief. That this must be the case is evident, if we reflect for a moment upon the nature of the effects which it is capable

of producing, and, at the same time, recollect that these effects are uniformly the same, but are modified by various circumstances. Thus, at one time, we find it operating exclusively as a stimulant, while at another it displays nothing but its sedative power. Given under certain conditions of the system, it quiets irritation, calms the pulse, softens the skin, and promotes balmy sleep. Under other conditions of the system, it quickens the pulse, suppresses the secretions, increases animal heat, and disturbs the brain. In the one case, the state of the patient is materially improved: while, in the other, it is rendered worse. It depends, then, entirely upon the circumstances under which it is given, whether it will prove salutary or injurious, and it is this which renders the proper use of it a matter which requires so much tact and experience.

Now, the circumstances which modify the action of this agent are numerous. Age, sex, temperament, climate, nature of the disease, stage of the disease, in short, everything which can affect the condition of the system, modifies, in a greater or less degree, its effects. To understand, therefore, completely the manner in which it operates on the system in its different phases, it is necessary to analyse all these modifying circumstances. On the present occasion I propose to make a few remarks upon only one of them *viz. age*, with the view of showing more particularly the peculiarities of its operation on the young subject.

With regard to the effects of opium on young subjects, there are two facts which seem to be well established. The *first* is, that it acts with much *greater energy* on the infant than it does on the adult: the *second* is, that it is more *uncertain* in its action on the infant than the adult. It is in consequence of these peculiarities attending its operation on the infant, that even the smallest quantities have not unfrequently produced the most unexpected and even fatal results. Of this, almost every physician must have seen some melancholy instances. Dr. John Clarke states, that "half a drachm of genuine syrup of white poppy, and, in some instances, a few drops of Dalby's Carminative, have proved fatal, in the course of a few hours, to very young infants." In one case, he says, forty drops of

Dalby's Carminative destroyed an infant. Mr. Marley says, "I have known three or four instances where the most dangerous symptoms were produced by Godfrey's Cordial and Dalby's Carminative; two nostrums which have no doubt added considerably to the mortality of infants." In a case that fell under his observation, the most rapid and alarming symptoms followed the exhibition of an ordinary dose of syrup of poppies. In another case, he knew half a small tea-spoonful of the syrup of poppies prove nearly fatal to a child eight or ten days old. Thirty-five drops of Dalby's Carminative he has known to prove fatal to a young child, while, in other cases, larger doses have been given without any unpleasant effects. The same writer relates the case of an infant, nearly poisoned, by considerably less than half an ordinary sized tea-spoonful of paregoric. Dr. Bard says, he once knew an infant of several months old killed by ten drops of laudanum, and another brought into very great danger by less than two drops. Dr. Montgomery states, that he has known more than one instance in which a tea-spoonful of the syrup has proved fatal to a healthy child. Professor Hamilton relates two cases, in which four drops of laudanum proved fatal to children some months old. Dr. Merriman reports two cases, in which a dose of Godfrey's Cordial proved fatal. He also states, that he once saw a child in the month, thrown into a state of excessive stupor, by taking one dose only of a mixture in which there were four drops of laudanum; the actual quantity swallowed could scarcely have amounted to one drop. Dr. Christison states, that "the administration of three drops of laudanum in a chalk mixture for diarrhœa, to a stout child, fourteen months old, was followed by coma, convulsions, and death in six hours." In another infant, a few weeks old, death resulted from four drops of laudanum. Dr. Ryan states, that he has known one drop of the "sedative liquor of opium" narcotize an infant. Of laudanum, two drops have been known to kill an infant, nay, in one case, a single drop destroyed a new-born infant. I have myself seen a young child narcotized by about twenty drops of paregoric. The foregoing facts are sufficient to show that opium acts with peculiar

energy and uncertainty upon the infant subject. The causes of this would seem to be the following:—

In the *first place*, the great difference in the physical organization of the *infant* and the *adult*. In the young subject the brain and nervous system are much more impressible, and the slightest causes, as we know, will sometimes derange them. Besides, in the infant, the circulation is more rapid—there is a greater proportionate quantity of blood circulating in the brain, and hence a much greater tendency to cerebral determinations. From these peculiarities in the organization of the infant, it happens that convulsions are so much more common in the early periods of life. Thus, for example, the irritation of teething—of worms or crude matters in the intestines, is frequently followed by convulsions. Intermittent fever, which in the adult commences with a chill, in the child is frequently ushered in by a convulsion. Scarlet fever, too, in the child, not unfrequently commences with a convulsion, while in the adult I have never witnessed such an occurrence. Now, with such peculiar predispositions characterizing the system in infancy, it may readily be conceived how it is that such an article as opium should act with more power at that period than in after life.

In the *second place*, the difference in the *temperament* or *constitution* of infants. In the adult, we know, as a matter of fact, that opium differs greatly in its effects in different constitutions. Thus, as a general rule, the sanguine temperament does not appear to bear the use of this drug as well as the melancholic or the nervous. In the former, it is much more apt to produce cerebral disturbance, and in large doses is more likely to prove injurious. Now, infants differ from one another as much, if not more, than adults, in these peculiarities of constitution, and, as a matter of course, the difference in the effects of this article must be greater. Besides, as these peculiarities and differences can only be detected by actual experience, and as we cannot of necessity have the same benefit of experience in the case of infants, it is obvious that the difficulty of justly appreciating the action of this drug on the infant must be greatly increased. A greater or less degree of uncertainty, therefore, must

necessarily from this cause attend its use in the early periods of life.

In the *third place*, the actual state of the system as to disease. There is no circumstance which modifies the effect of opium in so great a degree as this. In the adult, we see this continually. In some conditions of the system even small doses produce the most unpleasant effects, while in other conditions immense quantities may be given with little or no effect; thus, for example, when severe pain or spasm are present, quantities of this article can be borne which under other circumstances would prove exceedingly injurious. As illustrative of this, I quote an interesting case related by Dr. Percival. He states that a young man was admitted into the Manchester Hospital, on account of a violent spasmodic disease which recurred periodically in the evening, and after trials of various remedies, doses of opium sufficiently large to mitigate the violence of the paroxysm were ordered, and he took twenty-two grains every night during a week, without producing any soporific effect. On the eighth night he had no return of the spasm. He nevertheless took the opium, and in the morning was found dead. In this case a great and sudden change had unquestionably taken place in the nervous system of the patient, and to this must be ascribed the difference of effect. If in the adult the state of the system makes such a wide difference in the effects of this article, how much more so must all this be the case in the sensitive infant; and it is by not duly regarding this, that such unexpected results sometimes follow from the use of opium. Thus, for example, a child labouring under the acute pain of colic will tolerate doses, which, in the ordinary condition of the system, might prove destructive.

There is one condition of the young subject particularly in which this remedy is frequently resorted to, in which this is strikingly illustrated. I mean that state of exhaustion which arises from diarrhoea and other bowel complaints. In this state the head is very apt to become affected, and if opium be given with a view of checking the intestinal discharges, not unfrequently insensibility gradually creeps over the little sufferer, and in a short time death is the result; and this, too, even when the quantity used has been apparently

adapted with great nicety to the wants of the case. Every observing practitioner must have witnessed such instances. Now in many cases of this kind there can be no question that the child sinks under the sedative influence of the opium; and the reason is, that, in the exhausted state brought on by the disease, the system succumbs much more readily to the narcotic effects of this article, than it does in other conditions of the system.

The foregoing considerations appear to me sufficient to account for the greater power, as well as uncertainty in the action of opium on the infant, than on the adult.

If it be a fact, then, that opium acts in this way upon the infant, it appears to me to involve inferences of great practical moment, which cannot be too deeply impressed on the mind of the young practitioner.

1. That its use should *be avoided as much as possible* in the young subject. I will not say that it ought to be interdicted altogether, because, if used with discretion, it is a remedy of great value in many of the diseases of infants, but it should never be used unless there exists a strong and manifest necessity for it.

2. Great caution should be exercised in the form in which it is administered. No preparation should ever be used which is *not of a known and determined strength*. In England the *Syrup of Poppies* is the preparation most used for children. In this country it is also used, but not to the same extent. This is a pleasant and mild opiate, and on these accounts is well adapted for children. It is liable, however, to great objections. Besides being apt to ferment and spoil, it is very *variable in its strength*. On this account it is really a very dangerous article; and many cases are recorded (some of which I have already related) in which fatal results have followed the use of it, even in moderate doses. Another objection is, that it is liable to sophistication. Thus a mixture of *laudanum and simple syrup* has sometimes been sold for it. In the *LOND. MED. GAZ.* (May 1831, p. 253), a case is related, where a child died in consequence of a small dose of this latter compound having been given by the mother, who had previously given the same quantity of the pure Syrup of Poppies with advantage.

The best preparations for children are *laudanum*, and *elixir paregoric*. These are of known strength, and susceptible of division into the minutest doses. *Dover's powder* is another preparation, which may be given to children. It may readily be divided into the smallest doses, and it seems to act much more mildly than equivalent doses of simple opium. It need hardly be stated that all such articles as Godfrey's Cordial, Dalby's Carminative, &c. should be totally discarded from regular practice. Besides being uncertain in their strength, and on that account exceedingly objectionable, the sanction thus given to them encourages their use by persons out of the profession, who cannot be supposed to be acquainted with the dangerous effects of opium on the infant system.

3. In very young subjects, we should never begin the use of this article, except in *very small doses*. Although most practical writers lay down cautions about the use of opium in these cases, yet it does not appear to me that these cautions are sufficiently precise. Most of the writers to whom I allude specify doses as suitable to certain ages, without stating that even these doses may, in certain conditions of the system, prove just as injurious as much larger doses. To illustrate, I will quote the directions given by one of our standard authorities. Dr. Dewees says, "the proper dose of laudanum for infants and children, may be reckoned at the following rates. Half a drop for a child under ten days old; a drop, for one from that period to the end of the month; a drop and a half, or two drops, for one from that period to three months; three drops from this to nine months, &c. &c." "When laudanum is to be used as an injection, we may safely increase the quantity three or four fold." He adds, "these doses are prescribed for children who are altogether unused to the use of this drug; the power of bearing more may be rapidly increased by habit." Now, it appears to me that a more dangerous set of directions could not well have been given. Although many children may bear the quantities here specified without injury, yet every now and then a case will occur in which the most serious results will follow; and it is against these that the necessary precautions should always be taken. In

the case of a new-born infant, we are entirely ignorant of the manner in which such an article as this will affect it, and it therefore will not do to begin with *average* doses. To practise safely, we must feel our way with doses much smaller, and then we shall have some guide, and the only guide which the nature of the case admits of, to make the necessary increase in the quantity to be given. Under no circumstances as a first dose ought half a drop to be given to a child under ten days—or a drop to a child during the first month. One eighth of a drop is sufficient to begin with. The quantity, too, directed for an injection is too large. Instead of three or four times the quantity given by the mouth, as far as my experience goes, double the quantity is quite sufficient.

4. The doses of opium should not be repeated *at too short intervals*. This, too, is a point which is not sufficiently guarded by some practical writers. One writer, for example, after specifying the quantity suitable for a child of two or three months, adds, that “this is not to be repeated in less than an hour.” If this means anything, it means, of course, that after the lapse of an hour the dose may be repeated with safety. This, however, will not be sustained by experience. Even if a first dose does not narcotize, it frequently produces a degree of listlessness and indifference to food on the part of the child, which, if it be kept up by repetitions of the opiate, may eventually prove just as destructive. This is strikingly illustrated in those states of exhaustion from diarrhœa, where the due supply of nourishment is so essential to recovery. Where repeated opiates are necessary, the intervals between the doses should be long enough to enable the child to recover somewhat from the sedative influence.

Before concluding these observations, I cannot refrain from making a remark or two in relation to the use of this article by persons out of the profession. The mischief that is done in this way is incalculable. If, in the hands of those acquainted with its virtues, opium is an article so dangerous and uncertain in its action, what must it be in the hands of the ignorant? and yet we see it given to infants, day after day, and night after night,

by nurses and mothers, not merely without the consent of the physician, but sometimes contrary to his express injunctions.

There are two ways in which it is used by persons out of the profession, in both of which it proves injurious to the child. The first is by giving it in occasional doses; the second, by giving it constantly. The first is bad enough, but the second is still worse. The first, now and then, unexpectedly destroys a child; the second is followed by a train of the most disgusting consequences, worse, if possible, than those of habitual drunkenness in the adult. Fortunately, these latter cases are not of such frequent occurrence; occasionally, however, they are met with where the parent, for the purpose of quieting it, has been induced to keep a child for months under the daily influence of paregoric, Godfrey's Cordial, or some other opiate nostrum. In these cases, the effect is to stunt the growth of the child; it is emaciated and puny; the skin is flabby and shrivelled; the lips are bloated, and the countenance sallow and wrinkled. There is an absence of all intelligence, and the whole appearance is baggard and aged, presenting a sort of “miniature of old age.” Not long since I witnessed a case of this kind, in which a child of fourteen months old did not appear larger than one of two or three months. With the exception of one month, it had been kept upon paregoric almost every day since its birth. The mother was a poor woman, and on inquiring of her the reason, she stated that she had resorted to this method of keeping the child quiet while she attended to her work.

Of the extent of the mischief annually perpetrated by the unprofessional use of opium, some idea may be formed from a report made to the House of Commons, containing returns from the coroners of England and Wales, of the inquisitions held by them during the years 1837 and 1838, in cases of death by poison. The total number of deaths by poison in these years was 543, of which 52 were very young children, most of them at the breast, in consequence of opium, or some of its preparations, having been given by mothers and nurses, in ignorance of its effects. In addition to this, 20

more were destroyed by opium or laudanum administered in mistake for other medicines.

These facts are certainly appalling; and if any subject connected with medical police is worthy of the attention of the public authorities, it is certainly this. How the evil is to be corrected, it is not easy to say. Much, however, might be done by the proper dissemination of information on the subject. In most cases where opium is administered to children by persons out of the profession, it is disguised in the shape of some nostrum, so that they are not aware of what they are giving, and even when they are aware of it, they are not acquainted with the dangerous effects of it on the infant system. If parents and nurses were made better acquainted with the fact that such articles as Godfrey's Cordial, Dalby's Carminative, and most of our medicated lozenges and candies, owe all their composing properties to the opium which they contain, and that opium even in small doses is frequently a deadly poison to the infant, one would suppose that it could not but exert a salutary influence in correcting, to a certain extent at least, the evil of which we are speaking; and the dissemination of this kind of knowledge by the proper authorities would confer a lasting benefit upon the community.

I have thrown together the preceding observations because the subject is one of interest and importance, and because it appears to me that it has not sufficiently attracted the attention of the profession.*

INFANT POISONED WITH DOVER'S POWDER.

To the Editor of the Medical Gazette.

SIR,

ABOUT ten grains of Dover's powder were given, in mistake, to an infant seven weeks old. Twenty hours afterwards it died, with all the symptoms of poisoning by opium. By order of the coroner, I made a post-mortem examination of the body; and, should you consider the appearances of sufficient interest to merit a place in your valuable journal, you will greatly

oblige me by inserting an account of them.—I have the honour to be, sir,

Your very obedient servant,

THOMAS GRIFFITHS.

Hammersmith, March 4th, 1844.

Countenance placid; tongue and gums swollen and white; fingers of both hands firmly contracted; commencing lividity on abdomen; liver healthy in colour; colon much distended with flatus, and peculiarly white; bladder full of urine, and rising high above the pubes; spleen, kidneys, and intestines healthy.

The liver was gorged with blood. The stomach contained a very small quantity of colourless viscid matter. The inner coat very vascular at the great curvature; and in other parts were small patches of highly injected vessels. In the cavity of the abdomen was about half an ounce of fluid.

The lungs were gorged with blood, which ran freely from incisions made into them. The upper lobes infiltrated with greenish serum. The pericardium was very vascular, and contained about a drachm of fluid. The right auricle empty. The left auricle and right ventricle contained solid fibrin. The left ventricle some thin fluid blood, and a small coagulum. The thoracic aorta was partially filled with coagula. That blood which was fluid was remarkably thin and light coloured.

The sinuses of the dura mater were filled with dark coagula. The surface of the brain appeared covered by a complete net-work of vessels distended with light coloured blood. On the surface of each posterior lobe of the cerebrum slight extravasation had taken place. The brain was soft, and the difference of colour between the grey and white matter barely discernible. The vessels in the substance of the brain were gorged with blood, presenting, when it was sliced, a thickly studded appearance; the spots of a deep dull red, and in many places coalescing. There was a small quantity of fluid in each lateral ventricle, and along the floor of each were seen large distended blood-vessels. There was serous effusion on the surface and at the base of the brain, to the amount of about half an ounce.

A careful analysis of the stomach and its contents, with a view to discover morphia or meconic acid, was followed by negative results.

* New York Journal of Medicine.

TREATMENT OF BURNS.

To the Editor of the Medical Gazette.

Sir,

In two cases of severe burns of the hand, that have fallen under my care within the last three months, I have employed, with great benefit, the application of a single layer of lint soaked in a saturated solution of the "carbonate of soda." This simple remedy had the effect of completely relieving the distressing burning pain in the injured cutis, provided the part were kept constantly moist. In less than two hours all pain had entirely subsided, and the solution was no longer required.

I have conceived that, besides acting as a direct sedative upon the nervous structure of the skin, the carbonated alkali may possibly relieve pain by neutralizing the acidulous quality of the perspiration as it passes off through the irritated cutis.

As this information may prove perhaps useful in burns of a more extensive and serious description, by granting it a place in your instructive periodical you will much oblige, sir,

Your obedient servant,

FRANCIS PEPPERCORNE,
M.R.C.S.E.

3, Delahay St. Great George St. Westminster,

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

Principles of Forensic Medicine. Part I. and II. By W. A. GUY, M.B.

THE great importance of the subjects treated of in the two parts of Dr. Guy's work now published, induces us to notice them, before the appearance of the third and concluding part; which, moreover, being intended to embrace toxicology, may well merit a separate discussion.

It is many years since any complete treatise on forensic medicine has come from the pen of any British medical jurist; and even such as were, at the time of their publication, tolerably comprehensive, have by the mere progress of time, and the advances of science, as well as changes in laws bearing on the points of medical jurisprudence, become inadequate to the

requirements of the present day. The attempt to render the work of Beck, well suited as it may be for the American States, appropriate for English practitioners or lawyers, by notes of one editor after another, has only served to make it a mass of incongruities. We are well pleased, therefore, to find the entire subject taken up *de novo* by Dr. Guy, whose office, as well as the close attention he is known to have paid to many of the subjects individually, point him out as peculiarly well fitted for the task he has assumed.

The introductory portion of the first part contains some useful remarks on medical evidence, which should be carefully studied by every medical practitioner; for, we regret to say, there are few situations in which medical men appear to less advantage than in the witness-box. The remaining portion is chiefly devoted to questions connected with pregnancy, foeticide, and infanticide, matters which have been to a more than usual degree subjects of investigation of late, inasmuch as the operation of the New Poor Law has driven many unmarried females to attempt the destruction of their offspring; while the pressure of the times, and the difficulty of maintaining a family, have tempted even those living in wedlock to administer deleterious drugs to induce abortion. Every thing calculated to enable medical men to furnish the necessary information to guide the jury to a just inquiry, is supplied either in a tabular or other form.

Interesting and valuable as these are, they are less so than the contents of Part II. This refers chiefly to all points likely to be discussed when soundness or unsoundness of mind is the question. That some recent decisions in connection with atrocious crimes have lent an augmented importance to this subject, every one is aware; and no one can contemplate the probable result of the maintenance of the doctrines promulgated by the highest legal authorities, without dread. It has been already stated in this journal, that the late refinement touching monomania is the most alarming improvement ever made in psychology. All who coincide in this opinion must wish that the sentiment of the great and good Lord Hale, as quoted by Dr.

Guy (p. 267), prevailed in our courts of law—for we can scarcely designate them courts of justice—viz. “that all the circumstances of the case should be duly weighed, lest, on the one side, there be a kind of inhumanity towards the defects of human nature, or, on the other side, too great an indulgence given to great crimes.” The refinement which consigns individuals to comfortable quarters in Bedlam, instead of to the gallows, does not appear yet to have reached Scotland, where, notwithstanding the fondness for metaphysical subtleties and distinctions, the judges allowed Barclay (p. 228) to undergo the last penalty of the law, whose plea of insanity was at least as valid as that of Oxford and his followers.

The remaining portion of this Part is devoted to questions concerning death, sudden, violent, or voluntary; these are very ably handled. In fine, Dr. Guy's work may justly be looked upon as one of the most beautiful applications of anatomical, physiological, metaphysical, and chemical knowledge, to the elucidation of points of great interest to society and individuals, which we have had the good fortune to meet with. Doubtless the profession will express their obligations to him, by immediately procuring and studying it.

MEDICAL GAZETTE.

“*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas morbo veniendi in publicum sit, dicendi periculum non recuso.*”

CICERO.

THE MEDICAL PROFESSION.

A PURSUIT or calling must have in its nature something very valuable to mankind when its professors are treated with a large measure of personal consideration by their fellow-citizens, and its value must be still greater if that respect be shewn, notwithstanding that circumstances attending the exercise of the pursuit are offensive to the prejudices of mankind, or repugnant to the common notions of honour

and glory. Medicine and surgery are of this kind—at least in a highly civilized community—for many of the studies required are repulsive to public taste, and many of the duties performed repugnant to natural pride. Strikingly contrasted is it in this respect with the profession of arms, every detail of which is associated with ideas of honour and respect. The notions attached, however, to the exercise of our art, in a rude and uncivilized state of society, are exceedingly different; and this fact, with the reasons which give rise to it, should be borne in mind by those who desire to reconcile the very opposite impressions which are current respecting our profession. It is interesting as a mere abstract philosophical consideration, but it may also be highly useful in giving a just notion of our true dignity, and allaying those feelings of impatience and discontent to which nearly all are at times liable, but which, of course, are most apt to torment those who have much leisure for reflection, and too little philosophy to make a wise use of it.

To the ignorant and the savage, the physician is an object of worship; to the soldier, and to the settler in distant regions, he is a needful ally—the repairer of grievous injuries, or the restorer to health and strength. The country practitioner has the advantage, such as it is, of this distinction in civilization. His function is necessary to those amongst whom he resides, and he receives the homage justly due to his acknowledged usefulness. His social position, therefore, need give him no uneasiness; he is of necessity, during the exercise of his office, the confidential friend of all who consult him; and if his personal qualities be pleasing, and his mind cultivated, he becomes, moreover, the chosen companion of his most cultivated neighbours. But even if he have not these

qualities, his professional value is fixed and acknowledged.

An extreme case once came to our knowledge of a man who was by choice the daily pot-companion of the miners amongst whom he lived, who often mortgaged part of his fee for drink in the lying-in room, and spent the rest on his road homewards, yet who was so necessary to his rude neighbours that he was hardly ever unemployed, for the persons of refinement in the vicinity were too few to support a better man.

In the metropolis, on the other hand, where competition is great, and where men of the very highest celebrity live within reach, the case is exactly the reverse: practitioners in general are, no doubt, wanted; but there is no practitioner in particular who cannot be spared. How many fractures would remain unset, how many fevers unphysicked, if one-fourth of the chariots which flash through our capital were, within a fortnight, to deposit their learned owners at the termini of the railways, never to return? There are no doubt at all times, even in London, one or two, who are as much above public opinion as the Bibb of the mining district, though some eccentricity or asperity of manner may be the most obnoxious quality displayed; yet even these are much for a patient to expose himself to voluntarily, where politeness and good taste are the general rule.

But between the two extremes, of coarse demand for mere professional necessities, and a fastidious craving for professional luxuries, lies the large field of ordinary labour—a field cultivated by the great body of general practitioners—men who are amongst the most intelligent and deserving members of the state—in whom the most solid moral and intellectual materials have been worked up with much of the polish of a refined education. It is they who chiefly suffer

by any lowering of the professional standard in public estimation; and it is from the skill, the intelligence, the integrity, and common sense of these, that the public will form their ideas of the profession. From nearly all of the more public duties of magistracy and municipal government we have the privilege of exemption if we choose to claim it: it is only from those most wholesome and searching tests, private character and professional faithfulness, that society draws its conclusions with regard to us.

The real social position occupied by any profession will depend on the recognised demand which exists for its services, and the price which those services can command. This price includes not only the mere money value, but also the homage—the respect which men agree to pay to each other (*τιμή* means both honour and pay); and this will settle and arrange itself according to rules which, though apparently capricious, are, in reality, as fixed as any other natural laws. It would be a very bad sign indeed were we not to set a high value on our services, or, what is the same thing, not to exact a proper respect for our persons or our offices; but it is idle to talk of securing this respect by *à priori* legislation. If medicine or surgery should ever again be as much in request as they were in the time of Homer, the Podalirius and Machaon of that day would be just as celebrated. It has been well remarked, that any regimental assistant-surgeon of the present day could have cured half the wounds described in the *Iliad*: that is very lucky for humanity, and much to the credit of modern surgery; but then these gentlemen must be content to have their names mentioned in the *Gazette* and the *Army List*; only one or two in a century get places in the *Iliads* of their time.

But is there really no honour for the Doctor in these our days? Assuredly there is; but he must know where to look for it: namely, in the respect due to his private and professional character—in the consciousness of honourable usefulness—in the absence of all trickery and meanness—in a cheerful performance of the duties required of him—in the daily attempt to increase the value of the profession to which he belongs, by additions to his own knowledge and the general resources of his art. More, infinitely more, we are convinced, is to be done in this way, than by all the public meetings that ever were held—all the committees that ever were formed—or all the petitions to Parliament that ever were indited.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

Tuesday, February 27, 1844.

THE PRESIDENT, IN THE CHAIR.

An Account of certain Acute Diseases in the Throat and Larynx, one of which was cured by Tracheotomy. By JAMES ARTHUR WILSON, M.D. Physician to St. George's Hospital.

THE author commences by observing that, in the treatment of cynanche, the physician too often neglects the means which surgery affords for the relief of his patient, and that under the routine practice of bleeding, calomel, and tartar emetic, many have perished by suffocation, whom tracheotomy would have kept alive.

In Nov. 1830, he attended a gentleman of middle age, who died of cynanche, after three days' struggle for breath. The disease supervened on erysipelas of the chin, which succeeded an operation for the removal of some small warty tumors from the lower lip. On examination of the body after death, the epiglottis and posterior membrane of the tongue were highly vascular and thickened; the fauces and pharynx had a dull ashen appearance; their investing mucous membrane was soft and quaggy, from the infiltration of a dirty yellow pus in the subjacent cellular tissue; about the glottis the mucous membrane was disorganized, and beginning to separate by slough; the larynx, beneath the chordæ vocales, and the trachea in its entire length, were free from all thickening, undue vascularity, or other evidence of inflammation. About this time a woman died

in St. George's Hospital, with symptoms of malignant cynanche, in less than twenty-four hours after her admission. In this case the pharynx was thickly covered with lymph; the epiglottis was thickened, but in the larynx the inflammation had not extended below the chordæ vocales. Thus, in neither of these cases had the organic lesion passed below the level of the glottis; it terminated exactly *there*, so that an opening made between the thyroid and cricoid cartilages would have afforded instant and entire relief.

This reflection, to which the author was led by the anatomy of the disease, became, he observes, of the greatest practical use to him thirteen years afterwards in the treatment of the following case.

Mr. W. C., æt. 27, complained of slight sore throat on the evening of July 7, 1843. He afterwards attended a crowded assembly, where he danced much and perspired freely. On his return home he was unable to sleep from uneasiness of the fauces, and a sense of choking. At 10 A.M. July 8th, he was seen by Mr. Tupper, who ordered leeches and calomel, and as no relief had been obtained, at 2 P.M. 24 oz. of blood were taken from the arm.

At 7 P.M. the author saw the patient, who was then lying on his back, and breathing with great difficulty; by gesture he complained of pain across the larynx; the respiration was hurried, and there was a stillness of manner expressive of a dread of all movement; he seemed, moreover, fast lapsing into a state of coma. The operation of tracheotomy was resolved upon, and at 9 P.M. was performed by Mr. Keate. By an incision through the integuments, the trachea was exposed beneath the thyroid gland, and then divided vertically to the extent of one-third of an inch, and through this opening a canula was introduced. Instant relief was obtained, but before ten minutes had elapsed he was attacked with violent spasms of the chest, with a struggle for breath, as if from immediate suffocation; all consciousness directly ceased. The canula was immediately withdrawn, and the orifice in the trachea cleared from blood, and kept widely open. The breathing at length became more natural, and the face resumed the character and tint of life. Not long after this a large quantity of mucus mixed with blood was rejected from the mouth, and it was then found that the patient again breathed through the larynx, when the canula was with caution finally withdrawn. The patient gradually recovered his consciousness, and expressed by writing that his "breathing was quite easy." He slept at intervals during the night, and was convalescent from this time. Early on the following day, the voice was in some measure recovered by a low stridulous whisper. The fluids taken

by the mouth reappeared on more than one occasion with bubbles of air through the orifice in the trachea. Seven days after the operation the wound was closed by granulation.

The author observes that "nothing is more worthy of remark in this case than the immediate suspension of all diseased action in the throat and larynx, consequent on the admission of air into the trachea. The strain having been removed from the inflamed structures, they soon recovered their healthy faculty of nutrition to the system at large, every draught of fresh air becoming at once specific, and the process of cure was complete." He states that, for the future, he should in all cases be urgent (where delay was possible) for a sufficient interval of time after the division of the integuments, in which to staunch the blood, before the final breach of the trachea. The instrument generally to be preferred for this purpose is the trochar, and the method of performing the operation has been fully described by Dr. John Wilson, in the 25th Vol. of the Transactions of this Society, in a paper of high interest, entitled "Cases of Laryngitis relieved by Operation."

Since making the above communication to the Society, the author was consulted by Mr. Frogley, of Hounslow, in a case of laryngitis, in which the life of the patient was saved by the operation of tracheotomy. The case was that of a young lady, about 20 years of age, who after suffering some days from "influenza," was attacked with symptoms of laryngitis. They were at first relieved by leeches, calomel, &c. but at 2 o'clock in the morning of Feb. 7, Mr. Frogley was called in haste in consequence of an attack of stridulous breathing; the pulse was scarcely perceptible; the countenance ghastly, and the symptoms generally those of a person fast dying from suffocation. Under these circumstances Mr. F. at once proceeded to operate. A small incision having been made through the skin, immediately above the sternum, the subjacent cellular tissue was separated, chiefly by the blunt edge of the knife, and the trachea divided with little or no loss of blood; with some little difficulty the canula was then introduced, and immediately on the first rush of air into the trachea, the patient opened her eyes, and exclaimed "Oh! now I can breathe." Her complexion soon resumed its natural tint, and her voice its proper intonation; she swallowed with ease, and soon fell asleep, breathing tranquilly through the canula, which was secured by threads and adhesive plaster. The author saw the patient at 4 p.m. of that day, and found her without complaint, save a little pain from pressure of the tube, and finding that no air escaped through it, he directed its removal.

On the 21st Feb. a fortnight after the operation, the author was informed that "his patient was going on well; the wound all but healed, and she had not a single bad symptom." About 30 hours after the operation, she coughed up some dense membranous-looking phlegm, after which she did not breathe through the wound.

This being the Anniversary Meeting, the following address was delivered by the President:—

Gentlemen,—It is now my duty to take a retrospective view of the progress of our Society since the anniversary meeting in 1813.

First, of the financial report which you have just heard. The auditors are able to report favourably of the finances, even with the unusually large expenditure during the last year, for the increase and improvement of the library.

The additions to the library, by purchase, during the year, have been 100 volumes of foreign, and 60 volumes of English works; and by donation, the additions in the same period have been to the amount of 120 volumes.

Among the additions by purchase is the great and splendid work by Bourguery, on Human Anatomy, at the cost of more than fifty pounds. The Council, after much deliberation, decided upon the purchase of this work, which, from its costliness, is likely to be found in the libraries of but few private individuals; but which is so eminently useful as a book of reference on descriptive anatomy, containing, as it does, views of the regions of the body that are not merely repetitions of those already before the public, but very many of them wholly new, being the results of dissections which had not been before similarly displayed.

It appeared to the Council, from all the information they could obtain, that a reprint of the entire catalogue of the library would be of great utility. Accordingly, this work has been accomplished by our librarian, Mr. Phillips; and I am sure you will be disposed to accord your thanks to that gentleman for the considerable labour which he has so willingly bestowed on it.

I have the further gratification to announce the decision of the Council, that a copy of the new catalogue be presented gratuitously to each of the resident fellows of the Society upon application being made for it. The Council have been most anxious to decide wisely on this point; and it will be admitted to have required some consideration, when the fact is stated that, by the gratuitous delivery of the whole number printed, which is 500, the funds of the Society will suffer to the amount of something more than 150 pounds.

The present number of our resident fellows is 270. During the last year 35 fellows have been elected: a larger number has not been elected in any preceding year.

There have been received during the year the resignations of four fellows: Dr. Mantell, Dr. John Wilson, Mr. Samuel Cooper, and Dr. Roxburgh. Here are names which the Society will part with in regret, distinguished as they are in science. We can but wish that it had suited the convenience of these gentlemen to continue in the enjoyment of the advantages the Society affords.

Our list of deceased fellows contains the names of Henry Rumsey, Frederick Tyrrell, Dr. Macartney, Dr. Quarnier, Dr. Charles Thomas, William Money, and William Goodlad.

Henry Rumsey died in his 78th year, having practised at Chesham, in Buckinghamshire, more than 50 years. He is reported to have possessed an accomplished mind, and to have been, through his long life, an active cultivator of his profession; and there is evidence that this eulogy is well merited, in the paper which he published, exactly 50 years ago, in the Transactions of the Society for the Improvement of Medical and Chirurgical Knowledge, giving an account of Croup as it appeared in the town and neighbourhood of Chesham, during the years 1793 and 1794. It is generally acknowledged to have been a paper of great value, presenting, as it did, at a period when the peculiar features of croup were not generally known, an exact and vivid description of seventeen cases of the disease. It was of value, besides, as the means of introducing into practice the treatment of croup by emetics in doses to excite vomiting. Having related his unvaried failures by all other modes of treatment, Mr. Rumsey says he at length had the satisfaction of witnessing the recovery of a child after taking the tincture of squills and ipecacuan wine in such doses as to excite repeated vomiting. Another circumstance of interest in this paper is, that it introduced into this country the free exhibition of calomel, in addition to emetics, as had been adopted in America by Dr. Rush.

The professional career of Frederick Tyrrell is so well known to the Fellows of the Society as to render it unnecessary for me to enumerate the various public stations he so worthily filled. But there are points in the professional character of Mr. Tyrrell which call for particular notice on this occasion, as a just and proper tribute of respect to his memory. His life was one of incessant labour in the acquisition of scientific and practical knowledge; but it was the labour in which he delighted, urged on as he was by the conviction it must be the only safe road to professional eminence and public

favour. His principles were good, and accordingly his conduct was unsullied by a single unworthy act. The result was such as he had hoped for. At the period of his premature death he was rapidly acquiring the confidence of his professional brethren and of the public; and it is because merit here received its just and appropriate reward, that this brief notice of our lamented associate may, it is hoped, be the means of awakening a feeling of emulation in the minds of the younger members of our profession. There are, in our Transactions, two contributions by Mr. Tyrrell; one in the 13th volume, consisting of remarks on a case of injury to the head; the other in the 21st volume, consisting of a paper on the treatment of acute purulent ophthalmia. His principal contribution to medical literature was the elaborate work on the diseases of the eye, faithfully recording the results of his experience in the treatment of these diseases through the long course of observation he had enjoyed at the London Ophthalmic Hospital, to which he had been attached more than twenty years.

Of the professional character of William Money I have been able to discover only one public record, a work published by him on Morbid Anatomy, which, although it possesses the very unattractive title of a "Vade-mecum," is, nevertheless, a work of merit, containing, as it does, above 250 drawings of pathological changes, with an account of the symptoms by which they were accompanied.

William Goodlad practised with much and deserved reputation for many years at Bury, in Lancashire, and, during the last few years, in Manchester. The professional character of Mr. Goodlad will be best estimated by the enumeration of his public works: they are,—

An Essay on the Diseases of the Vessels and Glands of the Absorbent System.

A Critical Inquiry into the Nature of Local Nervous Affections.

Papers in the Edinburgh Medical Journal on the Origin of Calculi—On Purulent Ophthalmia—On the Treatment of Scrofula—and a Case of Inguinal Aneurism cured by tying the External Iliac Artery. And in the 7th and 8th volumes of the Transactions of this Society are papers by Mr. Goodlad, relating to a Case of Removal of a large Tumor from the Face and Neck, in which the Common Carotid Artery was tied. Here are materials enough to shew that, although Mr. Goodlad's sphere of observation was remote from the metropolis, his mind was equal to the highest efforts of surgery. He tied the external iliac and the carotid arteries at a very early period after the introduction of these operations by Mr. Abernethy and Sir Astley Cooper.

James Macartney is the next in the list of our deceased fellows of whom it is my duty to speak. It seems probable, as has happened to many distinguished persons in our own and in other professions, that the early education of Macartney was not for medicine or natural science, but that he afterwards turned from the path which had been formed for him into another to which his genius and capabilities instinctively led him. The earliest notice of Macartney that I have been able to obtain is that, in the years from 1799 to 1802, he was zealously occupied in human and comparative anatomy at St. Bartholomew's Hospital, and that he was probably the first Demonstrator in its Anatomical School under Mr. Abernethy. There he did not long remain; and it is probable that he quitted London at that period to undertake the duties of surgeon to the Radnorshire militia regiment, in which he remained many years. An Irishman by birth, Dr. Macartney had not resided in Ireland from his youth until the year 1813, when he became candidate for the Professorship of Anatomy and Surgery in Trinity College, Dublin, and, from his high reputation, was elected in preference to numerous resident and other candidates. He retained this office twenty-four years; and, having resigned it in the year 1837, did not, I believe, engage in any other public duties. His death was sudden, at an advanced age, it is presumed from apoplexy, in March 1843. Sir Herbert Marsh, President of the College of Physicians in Dublin, informs us it had been arranged that Dr. Macartney should read a physiological paper at one of the evening meetings of the College, and that casually meeting him in the street on the day in which he was seized with his fatal illness, Macartney stopped to say that his paper was ready, and to inquire on what evening he should be required to bring it forward. The name of Macartney will be transmitted to posterity as of one of the eminent physiologists of his time. And it is of some interest for us to know that he acquired this high reputation chiefly through the means of his zealous devotion to comparative anatomy. This was the labour of his life. When the Demonstrator in the dissecting-room of St. Bartholomew's, he was actively engaged in the dissection of animals, and he then commenced the formation of the museum for the illustration of the lectures on Comparative Anatomy which he afterwards delivered. The result of his labour, constantly directed to the object of attaining a knowledge of the structure and functions of organs in animals, was, that Macartney soon found himself able to announce the bold, as it was then untried, experiment of a course of lectures on Comparative Anatomy and Physiology. He gave such a course, through several years, in the

Anatomical Theatre of St. Bartholomew's; and here it should be noticed was the delivery of the first distinct course of lectures on comparative anatomy in any of the medical schools of the metropolis. But the subject was then new; the interest and the importance of it were not then sufficiently apparent to induce many students to attend Macartney's lectures. The few who did so were, I know, highly gratified with the interesting matter he introduced into them.

Another result of Macartney's labours in comparative anatomy was the production of his elaborate contributions to Rees' Cyclopædia, composed almost wholly from his own dissections, and abounding in original matter. Such especially were the articles on the Anatomy of Birds and Mammalia, the former containing, with other novelties, the first account of the peculiar mechanism in the leg of the stork, and of other birds which sleep standing on one foot, whereby the leg can be preserved in a state of extension without muscular effort, also the first description of the plexuses of blood-vessels in the legs of birds analogous to those which Sir Anthony Carlisle had discovered in the limbs of the tardigrade animals.

In the year 1810, there appeared in the Transactions of the Royal Society, the important paper by Macartney, on Luminous Animals in relation to the Phosphorescence of the Sea, in which he gave the first complete account of the animals possessing the property of emitting light, endeavouring to ascertain from what parts of their bodies the light issues, and what are the circumstances influencing its emission.

The next work in the order of its importance which Macartney published was the Treatise on Inflammation, the scope and objects of which are sufficiently known to render it needless for me to dwell on them. But it deserves to be noticed that in this work is to be found the first scientific view of the use of water as a dressing for wounds, ulcers, and inflamed parts, the universal adoption of which is the best proof of its excellence, and consequently of the advantage it has conferred on the practice of surgery.

In the last year of his life, Macartney, with undiminished ardour in the investigation of minute structure, produced, in the Transactions of the Royal Irish Academy, his Paper on the Minute Structure of the Brain in the Chimpanzee, and in the Human Idiot, as compared with that of the Perfect Brain of Man, the object of the paper being to shew that in every part of the brain the white fibres are arranged in plexuses enclosed in the grey substance in the same manner that the coloured substances are arranged in the ganglia of the nervous system, and which view of the anatomy of the brain is confirmed by the best microscopic observers.

An old and much-valued friend of Dr. Macartney reports of him, "that he was an ever-active and inventive genius, quite an original thinker, that his lectures were full of ingenuity, and constantly changing from the new matter he supplied to them. Hence they were discursive, no two courses being exactly alike. Enthusiastic himself, his great delight was to make his pupils enamoured with the scientific pursuit of their profession. "He maintained besides," continues his friend, "the character of genius by another quality; he was rather contentious, and consequently was often in hot water: such, however, were his sterling good qualities that no man had more warmly-attached friends. He was not covetous of wealth, for he spent his all in hospitalities and scientific pursuits."

Among other objects of Macartney's zeal for the public good was the removal of the prejudice against dissection, and he missed no opportunity of effecting this. I remember to have seen in the Museum at Trinity College an iron vase, resting on a marble pedestal, and stated to contain the ashes of the heart of Dr. O'Connor, with the following inscription upon the pedestal:—"Preserved by Dr. Macartney in respect for the memory of the man who, freed from superstitious and vulgar feelings, bequeathed his body for the honourable purposes of giving to others that knowledge which he had employed for the benefit of his fellow creatures."

Such was James Macartney; a man of a high stamp, an ornament to our profession; and chiefly so, not from the discoveries he made, or the improvements he introduced into it, but because he worked zealously through a long life at the science of medicine, irrespective of considerations of pecuniary gain, in subservience to a nobler object, the interest of the studies in which it engaged him, and the gratification they afforded him. In the classification of men by Lord Bacon according to the various motives which urge them onwards in scientific pursuits, Macartney would take his station among the paucissimi, ut donum rationis divinitus datum, in usus humani generis impendant.

OFFICERS AND OTHER MEMBERS OF THE COUNCIL FOR THE YEAR 1844-45.

President.—Edward Stanley, Esq. F.R.S.

Vice-Presidents.—Marshall Hall, M.D. F.R.S.; Theodore Gordon, M.D.; Richard D. Grainger, Esq.; Robert Keate, Esq.

Treasurers.—Samuel Merriman, M.D. F.L.S.; Cesar H. Hawkins, Esq.

Secretaries.—George Cursham, M.D.; Alexander Shaw, Esq.

Librarians.—R. B. Todd, M.D. F.R.S.; Benjamin Phillips, Esq. F.R.S.

Other Members of the Council.—Neil

Arnott, M.D. F.R.S.; T. A. Barker, M.D.; Sir James Clark, Bart. M.D. F.R.S.; Jon. Pereira, M.D. F.R.S.; John Webster, M.D.; John W. Fisher, Esq.; E. A. Lloyd, Esq.; Alexander Nasmyth, Esq.; J. G. Perry, Esq.; Martin Ware, Esq.

NOTE FROM DR. WILLIAMS.

To the Editor of the Medical Gazette.

SIR,

Your favourable notice of my "Principles of Medicine" demands my best acknowledgments; but perhaps you will permit me to explain the meaning of some passages which you object to as "inadvertencies."

In the preface I state that "scientific men are not, and cannot, be practical, *because they have had no experience*;" and the object of this statement is to suggest the obvious remedy, that scientific men should get experience. "Philosophers must descend from their transcendental positions, to consider details of practice and purposes of utility." (Preface.)

The other passages objected to are, one in which it is stated that "a distinguishing characteristic of the pus globules is their want of cohesion" (§461), and another passage in 470, which is noticed as being inconsistent with the preceding quotation, inasmuch as it is there said that "obstruction to the circulation of the lungs and liver, and consequent circumscribed inflammation of these organs, result from *cohesion* and consolidation of the globules of pus contained in the blood." But the appearance of inconsistency ceases when it is mentioned, that the cohesion of the globules of pus mentioned in the last passage, according to the observations of M. D'Arcet, takes place only when the pus has been decomposed by the action of air.—I am, sir,

Your obedient servant,

C. J. B. WILLIAMS.

Holles Street, Cavendish Square,
Feb. 24th, 1844.

NEGLECT OF THE SICK POOR IN SCOTLAND.

To the Editor of the Medical Gazette.

SIR,

THE zeal with which you have advocated the cause of the Poor in Scotland, induces me to solicit you to give the following note a place in your valuable journal.—I am, sir,

Your obedient servant,

JOSEPH BELL,
Surgeon.

Barrhead, Feb. 1844.

Previous to the month of August last year, the managers of the Poor in this parish

(Nalston, Renfrewshire), not only refused to provide either medicine or medical attendance to the poor, but even almost universally declined to allow them the most trifling alimient when labouring under disease. The utmost starvation could scarcely obtain a single penny from the poor's fund. During last autumn, when our poor suffered intensely from epidemic fever, after much solicitation, the managers of the poor allowed the medical men the liberty of granting in extreme cases of poverty and distress an order to procure provisions to the amount considered necessary, which was to be paid from the poor's fund. Though this system of relief subjected the medical men to very considerable trouble, in addition to their unremunerated professional services, yet they most cheerfully submitted to the task, inasmuch as it enabled them to confer much benefit on their suffering and starving fellow-parishioners. We hailed it as a very great boon to the poor, and augured from the step, that a more considerate and benevolent treatment of the poor was in contemplation. But, alas, we have found that our hopes were too sanguine, that we gave too much credit to the poor's guardians, who seem to act as if they considered poverty a crime, and viewed the starvation of its victims the soundest policy, and the most suitable economy.

At a late meeting of these gentlemen, they ordered the medical men in a very uncourteous and uncourteous manner to discontinue affording any relief to the poor, no matter how great the necessity of the parties should be found. If the wants of the poor had become less urgent, there would have been some excuse for this harsh proceeding. I regret to say the necessities of the poor are undiminished, and the consequences of the step which our managers have now taken need not be pointed out. To make, indeed, any comment upon such an act would be quite superfluous. The fact merely requires to be mentioned, to stamp the parish of Neilston with the most heartless inhumanity. In truth, the circumstance is sufficient to degrade our social position, and to remove us to a state bordering on barbarism. In order that the readers of the *MED. GAZ.* may form some idea of the cases of poverty which occur in this place, I beg to subjoin, from my note-book, an instance or two, in which relief was afforded during last autumn.*

No. 1. — August 30, visited Widow M'L—. I found herself and two daughters, one aged about 16 years, and the other

nine years, labouring under fever, and lying together among wood shavings, without any covering. They had neither blankets nor sheets; their shifts torn, and black with dirt. Another daughter, aged about 20 years, and a boy aged about six years, both convalescent from fever, sitting at the side of an empty fire-place. They had no fuel, and there was no furniture of any description in the house; every article had been sold to meet their exigencies. A daughter is employed in a bleaching work, but as she has only recently obtained employment, she has not as yet received any wages. Another daughter, who has just recovered from fever, has been working in a cotton factory since the 28th inst.

The family have not partaken of a morsel of food during the last 36 hours. I ordered them provisions to the amount of five shillings. On the 8th of September, I again ordered the same amount, as I also did on the 24th Sept., this making altogether fifteen shillings,—a sum trifling indeed when we consider the number of the family and the extent of their destitution. What, I would ask, is to be done in such a case? The only answer which can be given is, simply, that they must be allowed to starve and die.

No. 2.—August 31st—Mrs. M'Q.—I was requested to assist in operating upon her for ascites, this being the eleventh operation. She seemed to be in a most miserable condition both as regards her health and circumstances; has had no food to-day; has only some little oatmeal and a few cold potatoes in the house in the shape of food. We sent and procured her some brandy, which rallied her, and allowed us to proceed with the operation. She has resided in this place upwards of eight years, and has always been sober and industrious; is not on the parish funds; Her only support at present is a boy, aged 16 years, who only earns two shillings and sixpence per week, being not fully employed. When able herself, she picks cotton waste; but she has not been able to do much of late in consequence of her diseased condition. There is very little furniture in the house, and the body and bed-clothes are both scanty and miserable; in fact, little better than rags. She was ordered provisions to the amount of three shillings*.

Such instances may serve as a specimen of the cases in which relief was given by the medical men during the time they had that permission. I cannot help thinking that

* I beg to refer my readers who wish further information regarding the condition of the poor in this place, to a former communication which appeared in the *MEDICAL GAZETTE*, for March 11, 1842.

* This poor creature has been twice operated upon since, and now is allowed one shilling and sixpence per week from the parish funds. Her house rent is about £3 per annum. *How much has she to live upon?*

the gentlemen who compose the Board of Managers for the Poor do not believe that such cases of distress exist at their very doors; otherwise they would never have withdrawn the assistance to which I have alluded. I really have too high a notion of the benevolent feelings common to human nature to think that any person could knowingly commit such a violation of them. Whilst I am thus disposed to place the most charitable construction on the conduct and motives of the managers of the poor, still the hardship and the misery of the case remains unaltered, and cries urgently to be mitigated. Ignorance regarding the state of the poor of this parish, whether pretended or real, can scarcely be pleaded in extenuation, especially when correct information can be so easily obtained. It is as much the duty of these gentlemen, who take charge of the poor's funds, to ascertain the condition of their poor fellow parishioners, as to distribute *sparingly* the funds at their disposal. The assessment is by no means heavy, viz. 4½d per pound of the rental. This, I believe, has been the highest rate. Consequently the amount of assessment cannot be urged as a reason in favour of the adoption of a resolution which is so derogatory to our common humanity, and so disastrous to the poor. I sincerely trust the managers of the parish funds will either immediately retrace their steps, or adopt some other mode of relief, and wipe away the stain which at present is attached to the parish of Neilston. I would not wish by any means to be looked upon as one of those bewildered persons who hold the monstrous doctrine that the poor ought to change positions with the rich, or that poverty is the result either of the oppression of the opulent or of bad legislation. I entertain equal contempt for those visionary schemes which have been proposed as means of pauperism from society. We are told by the highest authority that the "poor will never cease to exist in the land." We are informed from the same source, in language not to be misunderstood, the nature of our duty to those who are in want. Both are the statements of divine truth. "The Scriptures," says an able writer, "delight to represent the poor as the peculiar objects of the compassion and care of God. They dwell on their sorrows and afflictions; and they seek to preserve an interest in their favour, not only by direct pictures of their suffering, but by those epithets and expressions of kindness and regard which connect them habitually in our minds with all those views which keep alive and cherish respect and compassion. They throw around the sufferer a sacredness which even the remembrance of past misconduct is not allowed to violate. Even the most unworthy are in

time of suffering presented to us as objects of our compassion."*

Thus, if we cannot prevent poverty, we can endeavour to assuage its pangs. It is equal madness, either in whig or conservative, to treat its victims as criminals. It is the duty of every man, whatever political opinions he may entertain, to minister, so far as his ability will permit him, to the wants of his fellow creatures. We are all joined together by certain ties of common brotherhood, and are all liable to change (and even that suddenly) our social position. Our maxim ought therefore to be, "to do unto others as we would wish others to do unto us." "He that contrives mischief," observes a quaint writer, "to another has all the reason in the world to expect it should return upon himself; for the prevention of which we should have recourse to that golden rule, 'Quod tibi non vis fieri, alteri ne feceris.' We are all made of the same mould, obnoxious to the same difficulties and dangers, and therefore had need to tread warily, lest we open a pit for ourselves to fall into. Little did Haman think that he was erecting a gallows for himself when he ordered one to be made for Mordecai. God often interposes, and retaliates the same measures to men who heap them upon others."

The late Dr. Macgill, in his "Discourses on Subjects of Public Interest," has justly remarked, "Charity, as it is the duty and true interest of man, is the best worldly policy, especially of the rich. There are other dangers to be guarded against in society, besides the idleness or improvidence of the labourer, and there are other and more pleasing means of inspiring a spirit of well-doing, besides that of treating men with severity, and speaking of them as outcasts."

The gentlemen who at present act as managers of the poor in Scotland do not seem to allow any such principle to guide their resolves. They appear to be actuated to a very great extent by the philosophic theories on the poor, advanced years ago by Lord Kames†. In his schemes of poor-laws, his Lordship does not seem to think that any great evil would arise from a few of the poor dying occasionally of want. For the example of such unhappy persons left to perish "will tend," he affirms, "more to reformation than the most pathetic discourse from the pulpit." This doctrine seems, even in this the nineteenth century—the boasted age of *liberalism*—to have gained complete ascendancy over the minds of those whose duty it is to minister to the wants of the poor. But they should not

* Public Provision for the Poor, by Dr. Macgill.

† Vide "Sketches on Man."

overlook the moral contained in the fate of Perillus, the Athenian.

No person who has attentively perused the statements which have been recently published regarding the state of the Scotch pauper, can hesitate to exclaim with a profound and philosophic writer of a by-gone age—"The poor man's condition is very deplorable: the devil and the rich persecute them; and they are left to the rage of beggary, cold, hunger, thirst, sickness, and all manner of excruciating torments, which are, in many instances, heightened by their own depravity."—(*Burt. Mele.* p. 207).

CAESAREAN OPERATION

SUCCESSFULLY PERFORMED

BY DR. ZILL, AT NUREMBERG.

DOROTHEA SPACHEL, æt. 33, four feet in height, deformed by rachitis, believed herself seven months pregnant, when she fell into labour the 23d May, 1843. When examined the waters had escaped. The spine was crooked; the right shoulder raised; the pelvis inclined forward and to the left; the right iliac crest raised; the femora curved, the belly prominent, and baggy. The vagina was moist and very narrow, and the finger easily touched the sacrovertebral angle. The os uteri was dilated to the size of a crown-piece. The pelvis was narrower on the right side than on the left; the anterior posterior diameter measured an inch and a half, the transverse was an inch less than natural. Baudelocque's measuring compass shewed little more than four inches from the os pubis to the spinous process of the last lumbar vertebra. The uterine contractions were strong; a portion of the head pressed on the orifice, but was not engaged. The foetal heart was heard distinctly. Embryotomy seemed more dangerous than the Caesarean section. This was therefore performed at 7 P.M. by an incision into the linea alba from the navel to the pubes, and a living male child of the full term extracted. The placenta adhered to the fundus uteri, and was easily and immediately removed. Very little blood was lost, and no vessels tied; a portion of omentum protruded, but was easily reduced. Five sutures and some long adhesive straps were applied without bandaging the body.

The woman did well, with the exception of a miliary eruption, and some suppuration at the wound, with sloughing of cellular tissue, and she went out for the first time on the 17th July. The infant also thrives, though not fed at the breast.—From the *Medicinisches Correspondenzblatt Bayerischer Aerzte*.

CASE OF RHEUMATISM IN THE HORSE.

THE subject of this case was a fine draught horse, working at a country mill in this vicinity; but, from arrangements of the owner, it was requisite that his horses should draw timber occasionally, which exposed them to the vicissitudes of the atmosphere, and often during the most profuse perspiration, as most in the profession are aware. During the wet and damp of November last, this horse, with others, had been more than usually exposed to the inclemency of the weather at that time. While occupied in drawing timber through some of these long and heavy journeys which often fall to the lot of a timber-carrier's team, there can be no doubt the sudden changes to which they are liable are often, if not always, the cause of this malady.

The horse which I have in view returned from a long and laborious journey on the 15th of November last, when every kind and proper attendance was paid to him by his waggoner, who left him that evening to all appearance in good health.

On the following day, the 16th, he was worked a short time about home, had his regular diet, and in the evening appeared in perfect health; but on the following morning, the 17th, he found him heaving at the flanks, and, on attempting to move him, was not a little surprised to find him almost a fixture. He had not eaten the whole of his overnight's food.

This was soon made known to the master, who, on seeing him, thought it might probably be an old nail left in his foot, which was setting up suppuration there, he having had a case of this kind not long before; so from this notion he was made to limp to the blacksmith's, on almost three legs, for a removal of the shoe. An examination of the foot soon convinced them that the disease was not there. Shortly afterwards I was called to him, and found him with a strong bounding pulse, accelerated breathing, coat fixed, extensive lameness of the near hind leg, with other concomitant symptoms of acute rheumatism.

I immediately bled to the amount of ten pounds, and administered a brisk cathartic ball. Fomentations of hot brine were applied to the lame limb almost every hour.

18th.—Much better—lameness almost subdued—medicine operating well. Continue the fomentations of hot brine.

19th.—Lameness quite gone—the faeces almost of a regular consistence. Discontinue the brine, to which I attribute so early a cure.—*Mr. Monday, in The Veterinarian.*

EXTREME ATMOSPHERIC HEAT.

I HAVE heard fifty places picked out as the hottest in India, but Calpee certainly was always one of them. Heat to the human constitution and feelings is a relative term. Dr. Clarke mentions the heat of his marches near Jerusalem; he states the height of the thermometer at 102 Sechem. I have been encamped, with a considerable force, in the "merry month" of May, on the sands of Mynpooree, in the Doab, in excellent tents of double flies; yet in spite of tates, for there was seldom a breath of air, the thermometer rose daily to 125! I have, on horseback, hunted wild buffaloes at midday in the same month, amongst the rocky wilds of central India; but I have never felt any heat that could for an instant bear comparison with that of the latter end of June at Calpee. On a cloudy obscure day it stood at 145°. In the shade, even to a stager like myself, the temperature was awfully sickening; and so fierce that, long after sun-set, I was compelled to forego my constant practice of sitting out in the open air. At half an hour after sun-set, the mercury stood at 150° in the open air in the square of the cotton of go-downs. At ten o'clock at night, after endeavouring to obtain relief from a couple of well filled mus-sucks, the air (when my body was somewhat cooled) was still so heated, that I felt as if I had been quietly immersed in a hot bath.

During the season, several natives died of the *coup de soleil*. One drummer, with two young women, fell dead from this cause within a few miles of the city. The native remedy is unique: the patients (if it can be thrust down their throats) are compelled to swallow a mixture of unripe mangoes roasted and pounded with salt moistened with water.—*Travels in Upper India, by C. J. C. Davidson, Esq.*

CREOSOTE IN THE VOMITING OF PREGNANCY.

DR. PITSCHAFT has found by numerous applications, that the following pills constitute a truly specific remedy for the vomitings which so cruelly torment most women at a certain period of gestation.

R Creosote, 15 centigrammes; powdered lyoscianus, q. s.; distilled water, q. s.

Mix and F. S. A. a perfectly homogeneous mass, to be divided into nine pills (of about 10 centigrammes each) which should be covered with silver foil.

He prescribes three per diem (morning, noon, and evening).—*Chemist.*

GERMAN DIPLOMAS.

To the Editor of the Medical Gazette.

SIR,—Is it a fact that German diplomas can be obtained for £25? If so, is there no way of putting a stop to such a proceeding?

A CONSTANT READER.

London, March 4, 1844.

[It is but too true that the evil does exist. Can our correspondent suggest any mode of obviating it?—ED. GAZ.]

ON DISEASES ARISING
FROM THE
DEFECTIVE EXPANSION OF THE
LUNGS IN EARLY YOUTH;

*Being the Gulstonian Lectures at the Royal
College of Physicians, delivered*

BY GEORGE HILARO BARLOW, M.D.

Fellow of the College, and one of the Physicians
of Guy's Hospital.

4.—THE manner in which narrowness of the left auriculo-ventricular orifice produces obstruction to the circulation in the lungs, and dilatation with hypertrophy of the right side of the heart, is too evident to require any explanation: we should, however, anticipate, in such cases, that as the impediment to the pulmonic circulation arises from an obstruction to the passage of the blood from the lungs, the seat of which obstruction is in the heart and not in the lungs, the development of these organs, and of the pulmonary artery, would not be so early arrested; and also, from the mechanical nature of that obstruction, that the injury inflicted upon the lungs and pulmonary artery, by the efforts of the ventricle to maintain the circulation, would be greater than in those cases which have been already noticed.

Robert M——, aged about 18, a patient of Dr. Bright's, in Lazarus ward. Admitted 23d of January, 1828. From his earliest years he had laboured under dyspnoea and palpitation of the heart. His face was livid; and it was thought by some that there was an opening either in the septum of the auricles or that of the ventricles. His pectoral symptoms became more urgent just before his admission; and at that time, or immediately afterwards, he became generally hydropic. The remedies employed were directed against this latter affection.

He died suddenly, four days after admission.

Sectio cadaveris shortly after death.—
The head was not opened.

Chest.—There were strong old pleuritic adhesions on both sides. On the left they were generally diffused over the surface of the lung; but on the right they were more partial, forming bands and bridles, and admitting of a collection of a quart or more of serous effusion, by which the lung appeared to have been for some time compressed, yet not so as wholly to exclude air. There was much oedema behind the pleura costalis. The substance of both lungs was of a deep-red colour, remarkably firm, tough, and fleshy; but everywhere pervaded by a small quantity of air.

The pericardium contained several ounces of clear straw-coloured serum, unmix'd with floating flocculi; but on the right auricle there were numerous small flocculent elevations of an opaque whitish colour, and which did not appear to be of very recent formation. The pericardium was rather injected; but this was probably from congestion.

The heart was large, greatly distended, and its extremity quite blunt. The increase of size was chiefly dependent on the right side, which was of more than double the size of the left, which was rather small than otherwise. The thickness of the parietes was about the same in both ventricles, those of the left by no means exceeding what was natural. The muscular structure of the right auricle remarkably developed. There was no opening in the septa. The edges of the tricuspid valve were considerably thickened. The chordæ tendineæ, towards the septa, were remarkably short, confining the valve back against it. The pulmonary artery was large, but its structure was healthy. Its valves were also healthy, but the corpora Arantii were very large. The auriculo-ventricular opening on the left side was much and rigidly contracted; the chordæ tendineæ being greatly thickened, and the indurated columnæ carneæ were attached to it, almost without any intervention of chordæ tendineæ.

The aorta was remarkably small, being about the ordinary size of the common iliac.

Abdomen.—There was a large quantity of clear straw-coloured fluid in the peritoneal cavity. The vessels of the peritoneum were injected from congestion. From the same cause the mucous membrane of the stomach was of a diffused and deep red throughout.

There were also obvious traces of congestion and inflammation in the mucous membrane both of the small and large intestines.

The peritoneal covering of the liver was thickened, rather opaque, and firmly adherent to the gland, which was puckered and contracted. The acini were of a light colour, preternaturally firm and bard. The spleen was large and firm. The kidneys healthy.

In the above case we have the hypertrophy of the right side of the heart, narrowing of the aorta, engorgement of the great veins, enlargement of the liver and spleen, with nutmeg degeneration of the former; ascites, general venous congestion, and anasarca, which were observed in the preceding classes; but here we find it recorded that the pulmonary artery was large, whereas, in the former classes of cases, it was for the most part small: the reason of which difference I believe to have been this,—that the defective expansion of the lungs not having been primary, but the result of the obstructed circulation arising from the rigid contraction of the left auriculo-ventricular opening, the development of the pulmonary artery was not so early arrested by the want of the natural stimulus to the lungs; whilst the obstruction to the passage of the blood being purely mechanical, the artery yielded before the powerful contraction of the right ventricle. Indeed, I am inclined to infer from the cases already described, as well as some which I may have occasion to adduce hereafter, that whilst pulmonary obstruction arising from defective expansion of the lungs, with narrowing of the air-passages, is accompanied or followed by narrowing of the pulmonary artery, that arising from contraction of the mitral orifice is for the most part attended by dilatation of the same vessel.

The following case, although death did not take place till the 44th year of the patient's life, is highly illustrative of the consequences of disease of the left auriculo-ventricular orifice occurring in early life:—

Lucy C—, aged 42, admitted under my care at the Surrey Dispensary in the summer of 1810. This patient had suffered from acute rheumatism when fourteen years old, and had from that time been always subject to dyspnoea and palpitation, both of which had latterly become much more urgent; and when I first examined her, there

was a well-marked bellows sound accompanying the first stroke of the heart, which was loudest to the left of the left mamma. The impulse of the heart was strong, but the pulse at the wrist small. She was also at this time troubled with very great irritability of stomach, and could retain very little besides effervescing draughts. She obtained partial relief; but again became a patient at the Dispensary in the autumn of the following year. She was then suffering with her former symptoms, which had much increased in severity: there was also lividity of the countenance, orthopnoea, and occasional sickness, though the last was not so urgent as upon the former occasion. There was severe pain in the left loin, which was generally attended with sickness. The heart's action turbulent, with a double bellows sound; but, as far as I could judge, no friction sound: bowels rather relaxed: urine very turbid, from deposit of lithates: some oedema of the legs.

She obtained but partial relief, and died on the 8th of December, 1811.

The body was examined, in my presence, by Mr. Nuttfield and Mr. J. Miles.

Section cadaveris, thirty hours after death.
—The head was not examined.

The lungs were generally tough and fleshy, especially the middle lobe of the right. Both lungs contained several masses of pulmonary apoplexy, which were most frequent in the upper lobes. There was considerable effusion into both pleural sacs.

The pericardium contained very little fluid; and, with the exception of a white patch on the surface of the attached portion covering the right ventricle, the membrane was healthy throughout. All the cavities of the heart were large, and their walls hypertrophied; but this was especially the case with the right ventricle. The tricuspid valve was rather thickened, and the auriculo-ventricular opening perhaps too small. The semilunar valves of the pulmonary artery perfect: the artery of large size. The mitral valve was much thickened, and the orifice contracted so as barely to admit the top of the ring-finger: from the appearance, however, of the valve and the orifice, it is probable that there was but little, if any regurgitation: the sigmoid valves seemed perfect. The aorta was small, but as far as it was examined, *i. e.* as far as the left subclavian, it was healthy.

The liver was large, and far advanced in the nutmeg degeneration: it was apparently beginning to contract. There were upwards of sixty gall-stones firmly impacted in the gall-bladder.

The kidneys were large, and appeared here and there slightly granular: this was particularly the case in the upper part of the left kidney, where there was a small angu-

lar calculus imbedded in the substance of the organ.

It would be easy to multiply illustrations of this kind; suffice it therefore to say, that in the last case we have an instance of the effects of contraction of the mitral orifice, both upon the lungs and the pulmonary artery, the diseased appearances being in other respects the same as before. It may, however, happen, that cases of a more mixed character will occur, and which may appear to belong at the same time to two or more of the classes which have been described. Of these, I am induced hastily to relate the following, which occurred in Guy's Hospital, under the care of my colleague Dr. Hughes, as it appears to throw further light upon the simpler forms.

James H——, aged 18, by occupation a whip-maker, a boy of short stature, admitted into Luke's Ward, August 20th, 1842. He states that he has had five attacks of rheumatism; the first and most severe occurring three years ago; the last, four months since: otherwise he has enjoyed tolerably good general health. His present illness came on about three weeks since, and without any assignable cause. He has always lived in London; and his occupation, laborious, required him to be constantly standing.

His aspect is dark and puffy. Abdomen large and distended. The liver is very large, its acute margin being easily felt as low as the umbilicus. He complains of pain on pressure at the scrobiculus cordis. Legs and scrotum are oedematous. Urine is not scanty, and of a straw colour, and not coagulable by heat. Tongue moist, and covered with a brown fur, with red edges. Pulse 110, soft and compressible. Chest is tolerably well formed, and resonant on percussion. On application of the stethoscope, the heart is large and powerful, the sounds being indistinct, and running into each other. Under the mamma is heard a prolonged bellows murmur; the second sound is there scarcely audible. On the sternum opposite the third rib is heard a *bruit de diable*, less loud and prolonged than the first, gradually increasing in intensity as the stethoscope is passed upwards in the course of the aorta. To the right of the sternum is heard a clear loud flapping first sound, distinct from the murmur previously named. The impulse is felt very distinctly in the scrobiculus cordis behind the enlarged liver, giving to the hand almost the feel of aneurism of the descending aorta.

He died on the 4th of September.

Secitio cadaveris.—I was not present at the inspection, but had an opportunity of seeing the heart and trachea.

There were extensive pericardial adhesions, some of them very old. The whole heart was large, chiefly owing to the size of the

right auricle and ventricle. There was much deposit under the lining membrane of the left ventricle, chiefly near and around the auriculo-ventricular orifice, which was rigid and contracted: the mitral valve was likewise much thickened. The left ventricle was of rather large capacity, and its walls of moderate thickness: the sigmoid valves of the aorta much thickened; and when the aorta was laid open, appeared almost of a triangular shape, having their bases attached to the sides of the orifice: the aorta was very small. The right auricle and ventricle were large and thick, but the lining membrane and valves were healthy. The pulmonary artery was of normal size, relatively to the size of the subject; but was small comparatively with the size of the ventricle, though large in comparison with the aorta. The trachea was exceedingly small: it would not admit the end of the little finger, and would have been considered small for a child of ten years of age. The liver was myristicated. The genitals puercile.

This case presents a remarkable combination of disease of both surfaces of the heart, with defective development of the lungs and trachea, and at the same time illustrates the influence of the latter upon the size of the pulmonary artery, for although we had in operation a great amount of obstruction on the left side of the heart, to the return of blood from the lungs, so great as to lead a distinguished continental pathologist, who once saw this patient, to diagnosticate dilatation of the pulmonary artery, it was nevertheless of but normal size, as referred to the size of the subject, large in comparison to the aorta, small in comparison to the right ventricle. It was, in fact, large when compared to the trachea, small compared to the obstruction in the mitral orifice; showing, in short, the opposite effects of these two causes upon the size of the vessel.

I believe that it would hardly be in accordance with the intention of these lectures, were I to enter into minute details of treatment, but without transgressing my limits I think that I am at liberty to observe that, if the reasoning which has been adduced be correct, there are practical inferences to be drawn from it of no trifling importance; these inferences are perhaps sufficiently obvious, though their application will require considerable judgment and caution on the part of the practitioner. Now, it must, I think, be evident that, in the first class of cases, those, namely, in which obliteration to the pulmonary circulation arises from defective expansion of the lungs and air-passages, occurring as a primary affection, and where there is consequently no organic disease at the first, the therapeutic measures must of course have reference to the period of the affection, and may, therefore, be di-

vided into the preventive, the remedial, and the palliative.

And first as regards the preventive means to be employed. These will, I think, be most readily suggested by a review of the origin and progress of the disease. Thus, a young person about eleven or twelve years old is observed to be short-breathed, perhaps to be troubled with a cough, and to be rather bloated in the face, and is perhaps sent home from school on that account. Measures in themselves judicious are very likely adopted, and considerable relief is obtained. The child perhaps returns to school, and the mother and governess, or tutor, and very likely the medical attendant too, comfort themselves in the belief that, if a boy, "he will out-grow it," and if a girl, "that when a certain change takes place," all will be right; but, somehow it occasionally happens, especially if the patient be placed under unfavourable circumstances, or the original disproportion be great, that the boy instead of out-growing his complaint ceases to grow at all; or, the expected change in the girl never takes place; and hypertrophy with obstruction of the circulation on right side of the heart, with the train of symptoms detailed in the case of Mary Kendal, are the consequence; or perhaps the boy does in some measure out-grow his complaint, or for a time appears to do so, and the girl attains to womanhood; but cough and dyspnoea, with perhaps asthmatic paroxysms occur, at first, most probably, after considerable intervals, but afterwards more frequently, and for a longer continuance, and ultimately become permanent, and either carry off the patient at a premature age, or render life a state of protracted helplessness and suffering.

It is obvious that preventive measures are available only in early youth, before the different regions of the body have maintained that relative proportion to each other which they are destined to maintain during the period of maturity. Those which appear the most appropriate are, to endeavour to promote the development of the respiratory apparatus, to maintain a regular and moderate action of the other excretory organs, and to obviate as much as possible all venous congestion by regulating the amount of the circulating fluid.

For fulfilling the first of these indications, a pure air is absolutely essential. An atmosphere loaded with carbonaceous vapours, or the exhalations from organic matters in a state of decomposition, not only by its disagreeable qualities tends to repress the healthy action of the lungs, but also acts, as has been already observed, as a direct stimulus to the liver; whereas, a pure atmosphere, free from such noxious ingredients, and containing the due proportion of oxygen,

is the natural stimulus of the respiratory organs, and must, therefore, tend to promote their healthy development.

It is, indeed, earnestly to be wished that an improvement in the drainage of many parts of our large towns, as well as increased facilities for ventilation in the alleys or courts inhabited by the lower classes, and a less crowded state of their houses, might exempt them from their present peculiar liability to this as well as many other forms of disease. At the same time, it ought not to be forgotten that the same noxious influences, though applied in a somewhat different form, are often to be found in operation amongst the children of the wealthier classes. The too close confinement to sedentary occupations; the crowding too many children into the bed-rooms at schools; the want of proper ventilation in school-rooms, and regulation of temperature; the neglect of all exercise in the open air, save a funeral procession round one of the squares of Chelsea or Brompton; the heated atmosphere of drawing-rooms at "children's parties" during the holidays, and above all the compression of the lower lobes of the lung by tight stays, or other parts of dress, are so many causes tending to arrest that development of the lungs and air passages, the accomplishment of which during youth is essential to health in maturer age.

Again, the regulated exercise of the system generally, as well as of the lungs in particular, must not be overlooked. The former not only by exciting gives tone and vigour to the vascular as well as the muscular system, but also, by increasing the rapidity of the venous current, calls the lungs into fuller action. It is almost needless to observe that if such exercise be carried to excess the effect will be one of the very evils which we are desirous of preventing, namely, the engorgement of the right heart; and therefore it is necessary that where there exists any tendency to the affection of which we are treating, all such exercises as produce palpitation of the heart, or any approach to lividity, should be carefully avoided. The inclinations of the patient, unless he be stimulated by emulation to perform some feat of activity or muscular strength, will generally be a sufficient safeguard. The exercise here recommended should also be taken as much as possible in the open air.

The advantage of exercising the lungs themselves is not perhaps in general sufficiently considered, yet no one can contemplate a child shouting in the mere joyousness of his young life and opening faculties, and not believe that he is obeying an instinct given by nature for some useful purpose. The advantage of moderate exercise of the vocal organs is equally great in early youth as in childhood, and perhaps the singing lessons are of some service in this respect,

though they do not generally commence at the time when the expansion of the lungs is of the most importance. Reading aloud is another means of expanding the lungs and air-passages; which is most beneficial, unless carried to excess:—and thus the acquisition of the most useful and agreeable of accomplishments may be made subservient to health. Upon the importance of a careful attention to the state of the excretory organs in childhood and early youth, it is hardly necessary to insist: at the same time, it may be well to recommend caution in effecting our purpose; for it must be remembered, that over stimulating leads often to disorganization. When the evacuations appear to be deficient in bile, or there is any reason to apprehend congestion in the portal system, a mercurial purgative will be most beneficial, but it should never be wantonly administered. A free and regular action of the kidneys should also be maintained: where they appear to act sufficiently, the use of diuretics should be avoided; but if, on the contrary, there appears to be any deficiency in the quantity of the secretion, the least stimulating means for the encouraging it should always be preferred. The beverage known by the name of “Imperial” I have found of service. Should more active measures be required, the acetate of potass may be employed; and where there exists, at the same time, any tendency to inordinate action of the heart, the tincture or infusion of digitalis, in carefully regulated doses, may be added; but it perhaps belongs more to the remedial than the preventive means. The functions of the skin should also be maintained by uniform and moderately warm clothing; and the cutaneous circulation may be further assisted by gentle friction. Care should also be taken to regulate the quantity of fluids taken into the system; as the rapidity with which fluids are absorbed through the portal circulation may give rise to considerable embarrassment to the right side of the heart.

Secondly, of the remedial means. By these, I mean such measures as are calculated to restrain the increase of the disproportion when it already exists; and thus to allow an opportunity for the healthy relation of the several organs to be restored, before the period when growth ordinarily eases. It must be admitted, that the signs of the affection are obscure: at the same time, I think that we may not unfrequently have tolerably satisfactory evidence of a deficiency in the respiratory function, dependent upon the causes which I have pointed out.

To relieve the lungs, by exciting to greater activity the liver, the kidneys, and the skin, is, I believe, the first indication to be fulfilled in such cases. The

next object must be, to control the action of the heart, and to prevent its embarrassment, either from a too great quantity of blood in the system generally, or its accumulation in the venous trunks; and, lastly, to favour the development of the defective organs, by such measures as have been already suggested. The means of fulfilling these indications must, for the most part, be left to the discretion of the practitioner. I cannot, however, pass unnoticed the great benefit which I have occasionally obtained from the combination of calomel, digitalis, camphor, and hyoscyamus. Moderate abstraction of blood will also be sometimes beneficial.

We must also bear in mind the liability of the patient to pulmonary apoplexy from any cause which may determine an increased quantity of blood to the right heart; and also to lesion of the tunics of the arteries, from any unusual excitement of the heart's action.

Thirdly, Of the palliative treatment.—When the organic changes, which have been described above, are fully established, the most that we hope is, to avert for a time the fatal termination, and alleviate the suffering of the patient by palliative means; which, however, cannot be expected to be of much avail, unless based upon a right understanding of the nature of the disease.

The great object, however, of relieving the lungs by means of the auxiliary excretory organs, should never be lost sight of: for this purpose, the bowels should be freely acted upon, and general diaphoresis maintained; and if free diuresis can be produced, we shall effect the purpose of carrying off redundant fluid, and thereby relieving the heart, whilst we are fulfilling the important indication just pointed out.

The principles which have just been laid down for the regulation of the treatment of the first class of cases, will, perhaps, apply with equal force to the second and third classes. In the second (that, I mean, in which the walls of the chest are morbidly contracted), as we never hope entirely to overcome that contraction, we must keep in mind that such a patient will always be unable to bear any condition of the system calling for a great amount of respiratory function.

The same holds good, that in third class, in which obstruction of the pulmonary circulation is the effect of pericarditis acting mediately through the impediment which it affords to the respiratory movements; but in our prognosis in such cases we must bear in mind the great difference between the consequences of pericarditis occurring before and after growth is completed; for in the latter case (as shown in the subject whose pericardium was found to be ossified), extensive adhesions may exist without any

serious inconvenience being the result, and in the latter the consequences are almost necessarily fatal.

In the fourth class, that I mean in which there exists morbid contraction of the left auriculo-ventricular orifice, the hope of affording much relief may appear still more feeble, and if we can expect to do so only by removing the structural lesion, it must be utterly desperate; but if we act upon the principle, that in this aperture, through which the whole blood of the body must necessarily pass, there is no room, indeed, for that of a muscular or very active system, but that the smaller current of a tranquil less developed one may be allowed to pass; and if too we bear in mind the importance of preventing the too sudden increase of the circulating fluid by due attention to the ingesta, and the power we possess of controlling it by means of the various secretory organs, we may yet effect much, very much, towards prolonging the life, and mitigating the sufferings of our patient.

It may, however, be thought that, in considering any class of diseases originating in early youth, I have been guilty of a great omission in not having before made more particular mention of the effect which must be produced upon the system by the occurrence of puberty, and more especially the establishment of the catamenia in females. Now I am well aware that this ought never to be lost sight of in such cases; but I am of opinion that a sort of mysterious importance is too often attached to the function of menstruation, and that its occurrence is often hoped for in cases where, if it actually were to take place, it would be the worst thing that could happen.

The truth is, that the connection between the respiratory and genital organs is more close than is generally supposed, and has more especial reference to those classes of disease which I have been considering than is commonly supposed; for it has been recently ascertained, by Andral, that the daily quantity of carbonic acid exhaled from the lungs increases in both sexes pretty steadily from infancy to puberty; but that then we observe a remarkable difference: in the male it begins to increase more rapidly, but in the female its increase is entirely arrested, and remains stationary so long as menstruation continues; but that whenever this function is suspended, or when it permanently ceases, the amount of carbonic acid undergoes a considerable increase.

Now, if these observations are correct, it must follow that the menstrual function must act as a relief to that of respiration, and that, consequently, where it is suspended, the lungs must be called into increased activity; and, consequently, that, in the diseases which have been described,

the suppression or non-appearance of menstruation must tend materially to aggravate the symptoms and hasten the fatal termination.

In confirmation of this view of the subject, I may remark, that in the case of Jane Gompertz, who lived twelve years after the first occurrence of the symptoms, menstruation was established, and continued regular for a considerable time; whereas, in those instances in which death occurred more speedily, it never took place, and that in the case of Lucy Castle, the original disease occurred at the age of fourteen, but that menstruation being established, the patient's symptoms did not become very urgent till about forty, the period at which that function began to subside. In the males, again, with one exception, the defective development of the lungs seems to have checked altogether that of the generative organs.

I had hoped to have been able to enter into the discussion of the second division of my subject, namely, the origin of tuberculous disease in the lungs in the period of early youth, from the increased function they are then called upon to perform, but the time compels me to forbear.

I am aware that many errors must have found their way into these investigations, and that need may arise for modifying many of the conclusions at which I have arrived in their prosecution; still, I believe that the inquiry itself is one of no ordinary interest, and I have thought it a fitting one to be the subject of these lectures; for although it may be the province of the physician to find safe counsel in the hour of immediate and impending danger, it is no less his duty to endeavour to foresee the storm which his art may be unable to quell.

RECORD OF CASES.

By THOMAS MAYO, M.D. F.R.S.

Physician to the Infirmary of St. Marylebone.

[Continued from p. 615.]

On Intermittent Disease.

THERE is no more interesting subject in medicine than that of masked intermittents, under which the presence of periodicity entitles a train of symptoms, differing in every other point from those of ague, to receive with advantage the treatment belonging to that disease. But there is another view of this modification of disease, not less important: I allude to cases of the above kind, in which periodicity has been clearly established, but the treatment appropriate to intermittents is not borne.

Many years ago I was consulted in respect to a lady, who had for some time been in weak health, latterly with a progressive increase of pallor, feebleness, and emaciation; and, what was most important, a daily recurrence of pain and oppression of the head, with some delirium. The paroxysm occurred always at about the same hour, and lasted three or four hours. Her natural constitution had been good, her person strong, her temperament not nervous, her age about 43. She had undergone much treatment among other physicians; she had consulted Dr. Abercromby, of Edinburgh. On careful inquiry I found that, seven years before, she had had ague; and I was led to believe that the treatment of it had been incomplete. On this supposition I directed, after securing just action of the bowels, which had indeed never been neglected, that 50 drops of *Tinctura Opii* should be given at about an hour before an expected paroxysm; and that after it should have subsided, five minims of *Liquor Arsenicalis* should be given every sixth hour. I regret that I have not more copious notes of this case; but I can affirm that the plan was rapidly and completely successful. In a few weeks this lady was well, though weak. I should observe that a squamous eruption, which had existed for some time on the calves of the legs, disappeared also under the above treatment.

The above case illustrates the well-known effect of treatment regulated on a presumption that certain symptoms are referrible to the presence of ague, where nothing but their periodicity could suggest such a presumption. In the following case an imperfect analogy occasioned me to try the same practice with less success. The periodicity was established, but the treatment appropriate to intermittents was unsuccessful.

Peter Weller, a coachman, aged 60, of respectable appearance, thin, but muscular, dark in complexion, came into the Marylebone Infirmary on the 23d of May, 1841. He had twice, in the course of that afternoon, been attacked by vertigo and hemiplegia of the left side, with loss of speech, each time recovering the use of his arm and leg, and of his speech, in about the same degree. Cupping to the nape of the neck, to eight ounces, four grains of calomel *h. s.*, and an aperient draught for the next morning, were prescribed by an officer of the house.

24th.—I found his pulse slow and oppressed; the hemiplegia had not then recurred; his bowels had not acted. I ordered—

Hyd. Chlorid. gr. ij. bis.

25th.—The paralysis had recurred this morning. *Cucurb. crucatæ* were imme-

diately employed *ad 3vj.* I found him relieved, but pulse still sluggish and oppressed. It is to be observed that the paralytic affection ceased as soon when depletion had not been applied as when it was.

Sumat Hydrarg. Chlorid. c. Jalap. gr. xv. statim; the bowels being confined.

26th.—Another paroxysm this morning. The attack comes on with rapidity; but he seems to know when it is coming on, his eye twinkling, then his mouth becomes drawn, then his speech and limbs failing; his head hot. The powder had freely opened his bowels.

Lotio frigida capiti. Liqueur Arsenical. ℥ij. ; Mist. Camphoræ, ʒiiss. ter. Hydrarg. chlorid. gr. iij. o. n.

30th.—The attacks continue daily, lasting about an hour. Pulse 84 (it had been 65), of sufficient strength; less oppressed. Tongue dryish, and becoming coated.

Perstet.

June 1st.—Much the same. The attacks occurring early in the morning, let him take—

Pil. Sapon. c. Opio, gr. x. h. s.

2d.—Soon after the pills were taken he became very heavy, his head hot; the paralytic state came on gradually through the night, and did not cease in the morning; his pulse still 84, firm. 6 leeches were applied to his temples, and after them, immediately, 2 blisters. The arsenic was discontinued.

3d.—In a continuous state of aphonia and hemiplegia; pulse 76, strong. He understands what is said to him.

Hydrarg. Chlorid. gr. v. 6tis horis ad 3iam vicem.

4th.—Much better to day; gums affected. Pulse softer.

Mist. Ætheris Comp. ʒiiss. bis quotidie.

6th.—The improvement, viz. in his looks, in the state of his pulse, and in his articulation, continues; but the hemiplegia of arm and leg is unabated. His state is no longer paroxysmal.

Hydrarg. Chlorid. gr. iv. h. s. Ol. Ricini, ʒij. sequenti mane, are occasionally given when the bowels are confined.

Between this date and the 19th of June he experienced a slight attack of pneumonia. Towards the conclusion of this attack, which was treated with leeches and *Potassio Tartrat. of Antimony*, he perceived shooting pains in the left arm and leg, these being still motionless. On the 27th he had obtained some motive power in the leg, and about the same time much irritability of bowels occurred. This having been appeased by aromatic con-

fection, he was (July 2d), taken with extreme coldness, pallor, and *appearance* of depression; his tongue, however, good; his pulse 84; his skin rather hot. Out of these symptoms he emerged in a few days, Hydrarg. c. Creta being given twice a day with the confection, and resumed a pulse of 65.

During the period which elapsed from the above date to August 28th, motive power was gradually increased more to the leg than to the arm; his general health was also improving. From the 12th of July to the 28th of Aug. he was taking Strychnie, gr. $\frac{1}{12}$ ter quotidie, with the omission of three days, during which his head having become heavy and his bowels confined, a blister was applied nuchæ, and fifteen grains of jalap with four of calomel were given. His bowels were otherwise kept open by colocynth pills. The urine sufficient in quantity, acid, and at no time albuminous. At this time I lost sight of this patient. He certainly was not yet restored to that integrity of power, which he was enjoying at intervals, when the dose of Pil. Sapon. c. Opio changed, or appeared to change in the manner described, the type of his disorder, and gave it a very undesirable freedom from intermission. His diet was throughout unstimulating, and moderately nutritious.

Such was the result in the case which I have last described of a practice founded on imperfect analogy. The remedies applied to its intermittent phenomena met with a condition of brain which rendered them inappropriate, and, it must be confessed, injurious.

In regard to that case which I first narrated, I have been informed that the patient about three years after died apoplectic. Whether her death was connected with her past disorder I did not learn. Were this the case, the event may have been induced in either of two ways. The intermittent symptoms may have returned indeed, but may have been overlooked under cover of the cerebral disturbance; and this state may have been treated with misplaced depletion. Such had indeed been the treatment used, before I first saw the patient. Or, again, the remedies by which she was successfully treated under my care, may have been repeated under an altered and unsuitable state of the cerebral system. Thus used, they may have been as unsuccessful or pernicious, as a similar treatment would probably have been in the case of Weller.

Considerations of the above nature

must be entertained if we would answer the practical question, what is that group of symptoms which, combined with periodicity, entitles the intermittent to be treated as an ague? a question forcibly suggested by one case, *inter alia*, which Sauvages furnishes. "T. R.," he observes, "had laboured under a quotidian for six months: after a night of prolonged restlessness, a paroxysm of epilepsy occurs at the same hour as, and in place of, the expected paroxysm of ague; and in this way, from that time, the disorder continued to run its course without any recurrence of the original symptoms." This case is valuable, not for its peculiarity, but rather as illustrating a *large* class, in which, the periodical character of the disorder remaining, the treatment by bark, or steel, or arsenic, &c., is questionable.

It has been judiciously observed, in regard to those intermittents in which the affection of a given organ is marked sometimes even more strongly than those symptoms which characterise the disorder as an intermittent, that the affection thus evolved or brought out by the miasma may require a special treatment, distinct from, possibly at variance with, that which its simple periodicity would suggest. In this point of view the supposed affection may be less appropriately called a masked intermittent than a tendency to phlegmasia, brought into an active state as often as the system is disturbed by the paroxysm of the intermittent. This disturbance of a supposed inflammatory nature may not, however, terminate with the paroxysm; but the system may be brought gradually into a condition in which the intermittent type may be lost, and a continuous disorder substituted.

The same discriminative tact is wanted here as in another equally indefinite disorder—hysteria—in which a phlegmasia may easily combine itself with the nervous affection: a view of the subject, I apprehend, far more frequently applicable than that suggested by the terms *simulating*, *proteiform*, &c. often used as descriptive of hysteria. The disorder which this hypothesis represents as *simulated* is really *existent*, and must receive its own treatment, modified by the judgment of the practitioner as he best may use it.

The above remarks may claim some

importance in relation to the present state of intermittent disease. Ague certainly has declined in frequency. But may we not in some degree exaggerate the effect of presumed improvement in drainage and cultivation of land as the cause of this diminution? Is it not in some degree a simple change in the form of an epidemic?

The frequently intermittent type of neuralgic disorders, their general susceptibility of benefit from those remedies which are specific in agues, is obvious. But it is scarcely conceivable that so great a change should be effected in some of the features of periodical disease as the substitution of headaches, or of an epileptic seizure, or of a nervous pain, for a rigor with its subsequent febrile accession, without grounds being, at the same time, afforded for a careful revision of our practice in these varied circumstances. Nor is this consideration weakened even by the remark of Dr. Macculloch, in his valuable work, "that the use of the most energetic remedies" is, in the neuralgic intermittent, "*precisely the same* as in intermittent fever."

The questions to which an inquiry of this kind would give rise are twofold. 1st, How far the specific remedies of ague preserve their ante-periodic influence under these altered circumstances of the disorder? *

2dly, How far this antepericodic influence is, in such cases, safe or beneficial?

3dly, What other remedies have acted with apparent benefit in such cases, as ante-periodics?

[To be continued.]

CONTRIBUTIONS TO THE PHYSIOLOGY OF THE HUMAN OVARY.

By CHARLES RITCHIE, M.D. Glasgow.

(For the Medical Gazette.)

[Continued from p. 740.]

PART II.

Dissections of the human ovary in individuals who had been pregnant, the ovaries being examined at different periods of utero-gestation, or after delivery.

* Dr. Hunt, in his recent work on Tic Douloureux, has exhibited an intimate acquaintance with these remedies in the above relation.

SECTION I.—*Ovaries of parties either supposed or really pregnant, examined before the completion of gestation.*

1.—M—, a very robust woman, brought into Fever House speechless, and died in twenty-four hours. In the uterus, which was not, however, more than usually vascular, was a cyst, of the size of a raisin, connected for about a third of its periphery with the anterior wall immediately above the cervix, from which it could be easily separated. Viewed with a common magnifier, it appeared to be a thin vascular bag, containing fluid, and enclosing, at its lower part, a circular vesicle, of about twice the size of a mustard-seed, while, throughout the cavity of the uterus, there was a considerable layer of dirty-looking jelly-like substance. Both tubes were very vascular, and full of the fluid found in them generally, having the colour and consistence of semen masculinum, or thin arrow-root, diffusible in water, and, examined by the microscope, consisting of innumerable very minute globules, aggregated into masses generally of an oval form, and differing specifically in appearance from the globules of blood, or pus.

First ovary exhibited, at one part, an old cicatrix, covered by a very thin white pellicle, and, at another, a small orifice, from which fluid escaped on pressure; and, corresponding with the former, there was, internally, a thin, empty vesicle, with inky coats, and with the latter, a more recently burst, and vascular flaccid vesicle.

In the *second ovary*, the tube of which was larger than the other, more vascular, and better filled with white fluid, which could be made to flow out copiously from the pavillon, there was an apparently recent opening, leading into a cyst of the size of a swollen garden-pea, filled with a clot of florid blood, and which consisted, first, of a distinctly-marked, delicate, transparent membrane as an outer capsule, exposing on its removal a granular-looking, whitish-yellow substance, enclosed within two other very delicate membranes, one being externally in connexion with the capsular investment, and the other internally in contact with the clot. Viewed from without, this substance had a convoluted look, and shone through its pellicular external covering precisely as the convolutions of the brain

do through the arachnoid. The pellicle was painted with exceedingly minute vessels, filled with florid blood, and in the sulci of the convoluted body were blue or dark coloured points, resembling very much the appearance presented, so far as colour and general effect, or contrast with the whitish convolutions is concerned, by the veins of the brain; while, viewed from within, the granular aspect and whitish colour of the convoluted body were exchanged for the appearance, as seen through the inner pellicle, of a uniform coating of an ash colour.

2.—Preparation 367 of R. R. Glasgow Hunterian Museum.

A fallopian tube conception at about the sixth week, with ovary of same size opened vertically along its centre. Situated deep in one of the segments of the ovary is an empty Graafian vesicle, which would admit a garden-pea, and on opposite segment is a small portion of the walls of the vesicle laid back. These are lined by a thin pellicle, which, at the bottom of the cavity, is indented into delicate grooves, without displaying any other appearance than might be supposed to mark an unbroken Graafian follicle of large size laid open by the knife in dividing the gland. External to both divisions of this cavity, and in each hemisphere of the ovary, are the segments of two long lemon-coloured bodies, of the kind described in this paper as cephaloid or cerebriform bodies, having the yellow matter traversed along the long axis of each by a white opaque line, formed either by thin internal pellicular lining membrane, or by lymph.

3. Preparation 52a of R. R. Hunterian Museum.

A uterus with both ovaries laid open, the inner surface of the former rough, and described in catalogue as a gravid uterus, and the latter as containing five corpora lutea, and some vesicles. In one of the largest of the former bodies contained in the right ovary there is a pellicular lining covering a thin film of convoluted yellow matter lying on the outer coat, which is thickened; but no contraction has occurred in this, or, with one slight exception, in any of the other cysts, which, as examined without dissection, appear to consist simply of an outer thick coat, having a delicate pellicular lining.

4. Mrs. C—. Had not menstruated

for three months. Symptoms of menstruation, or of abortion, two days before death, of fever. Uterus slightly enlarged, and what was supposed to be a portion of decidua projected from its orifice. The left side of its inner surface was quite smooth, and free from any membrane; but in the right cornea, and adjacent to the extremity of the tube, was a vascular opaque bag, of nearly two inches in length, which contained loose blood only.

Right ovary.—Externally, two small orifices, both permeable to a bristle, but old; some cicatrices, and several shreds of recent fibrinous tissue, the result of inflammation. Internally, one of the foramina communicated with a cyst consisting of a delicate inner membrane, and a thin layer of convoluted, brainy, yellow, exterior substance, and containing a coagulum of red blood. The other foramen was connected with a similar cyst, but having its blood absorbed, and its coats of a coal colour.

Left ovary almost generally enveloped in a fine expansion of new tissue, and the corresponding tube, though pervious, was adherent to two hypertrophied Graafian vesicles, each the size nearly of a hazel-nut, which protruded from the free edge of the gland. The surface of this latter was smooth, and without any visible foramen, and at one part was elevated into a nipple-like point, of the size of a marrowfat pea, on cutting into which a rapid squirt of fluid, apparently reddish serum, escaped from it, and a cyst consisting of a large bed of convoluted, or granular, fatty-looking, yellow, brain-like substance, came into view, communicating, as was now ascertained, with the exterior by a minute opening, through which a bristle was introduced. In the interior of this cyst, but without any organic union with it, was a substance which resembled very strongly an empty Graafian vesicle, the walls of which had become opaque, thickened, elastic, and corrugated.

5. Mrs. P—, mother of several children; three months pregnant. Aborted during fever, of which she died. Uterus enlarged to about twice its unimpregnated size. Orifice about an inch in length, and admitting finger with facility. Tubes filled with white fluid, the left being perceptibly larger

than the right. Ovaries longer and narrower than usual.

Right.—Had externally three cicatrices with ecchymosed and still tender surface, the most recent perforated by a small foramen, which led into a partially obliterated yellow cyst, containing blood.

Left.—Proximal extremity occupied by an old cicatrix, and distal by a tumid and slightly vascular appearance, surrounding a capillary sized opening, having in its vicinity two minute vesicular elevations, like those which are seen under puberty, or during suppressed menstruation. A little transparent fluid oozed from the opening on the introduction of a bristle, and on cutting into this there was exposed a circular cyst, of the size of a marrowfat pea, within which, but without any organic or other connexion with its inner surface, was a whitish globular body, resembling in its aspect an empty thickened vesicle, and in its tissue the fibrin of the blood having the colouring matter absorbed. The cyst itself did not appear to have begun to diminish in size, and was of a rhubarb colour, its walls consisting of a delicate pellicle, covering the yellow matter, and not differing in respect to general appearance, thickness, colour, or structure, from those of the same bodies in the unimpregnated state.

5A. Preparation 182, R.R. of Glasgow Hunterian Museum.

A uterus between the third and fourth month, injected yellow and black; the child seen through the amnion with its head pressing against cervix uteri. Right ovary contains a large triangular cyst in its free extremity, which consists of a cavity nearly the size of a small grape, lined by an opaque membrane, which, examined from its interior, has the appearance of a cobweb-like pellicle, and at its cut edges, and, as seen through the glass, that of a soft tissue, of about the thickness of silk paper, or of the amnion membrane; and exterior to this is a bluish, opaque, and, in some places, faint yellow-coloured, annular portion, of about the eighth of an inch in diameter, of a very delicate structure, permeated by black and yellow vessels, some of which have given way. No corrugation of the cavity has taken place.

6. ———. Abortion at the

fourth month; and death in a few days from fever.

External surface of ovaries pale; and exhibited some nearly faded cicatrices, and a few very minute, transparent, vesicular points, embedded in the peritoneal coat, along with others of a somewhat larger size, the vessels of which contained blood. The interior of the ovaries presented many similar ovisacs, and one thin, empty vesicle, the coats of which remained dyed yellow and black. The only other appearance was that of a fabiform, cephaloid body, seven lines in length, situated along the free edge of one of the ovaries, which, when cut through its centre, displayed in both of its segments a lateral fold of yellow matter from one to two-eighths of an inch broad, agglutinated in the middle, or the long axis of the body, by a white opaque line. The external investments of this body were of the most delicate description, and when separated by gentle tearing with the forceps under water, one pellicular coat covering the external aspect of the yellow matter was all that could be demonstrated. In the yellow matter itself no blood-vessels were detected; and on separating the white central line, each segment of the body opened up into a cavity lined by a cobweb-like membrane, constituting, when viewed unitedly, a cephaloid cyst identical with those found in the virgin female.

6A. Preparation 180 R. R., Glasgow Hunterian Museum.

An uterus about the fourth month; the veins injected black, and the arteries red. A body in one ovary, formed of a semi-opaque, fawn-coloured portion, interspersed by vessels, and encircled by an irregular ring of veins particularly; while, from within, it has several white striae penetrating it from an internal cavity, about the size of a pea, which is lined by a dense white membrane, the cut edge of which is nearly of the thickness of the paper called Bristol board.

7. Mrs. ———, seven months pregnant; died of apoplexy thirty hours after delivery.

Surface of both ovaries covered with a great number of minute red vesicles; and in each ovary there was a corpus cephalodium of the size of a pea, one of which, near which were the remains of a recent cicatrix, was fresher looking

than the other; but both presented the convoluted brain-like matter seen in the unimpregnated female, only in a more plump, vascular, and organized state. The inner surfaces of both bodies were agglutinated together by an opaque, unorganized, cobweb-like, but consistent matter.

Unbroken Graafian vesicles, in various states of advancement, but all small, were seen in both ovaries.

8. Mrs. C., a phthisical woman, aged 25; seventeen hours delivered of a living child at seventh month.

Right ovary was large, and faintly marked with numerous superficial fissures; also with a very vascular cup-like depression, consisting of a hard florid ring surrounding a dimpled point, shewing a healed foramen in its centre. Another hard pisiform body, with a few vessels on its peritoneal covering, and, at a little distance from it, a deep cicatrix, having two minute red vesicles projecting from its surface, were the only other external appearances. Corresponding to the first-mentioned tumor there was, internally, a cephaloid cyst of the usual appearance, but inclosing within it a dense, opaque, empty vesicle, similar in structure to the corpora albida. The second tumor was constituted by a body having a remarkably massive development of the brain-like matter, but destitute of an internal opaque coat, or enclosed cyst; and under the deep scar of the exterior was a white body in process of absorption; and throughout the gland, numerous undischarged vesicles of various sizes.

Left ovary marked externally by Graafian vesicles of small size, either approaching the surface as bluish maculae, or recently burst, and leaving a superficial blistered surface. Interior contained numerous vesicles, and two white bodies.

9. Preparation 52 R. R., Hunterian Museum. A woman who died undelivered in the ninth month of utero-gestation.

Ovaries contain three bodies, described in catalogue as corpora lutea. The uppermost is of an oblong form, and has a convoluted but very white tissue, with a deciduous or flocculent lining, and seems to be a cerebiform body deprived, by long immersion, of its colouring matter. The other two consist each of a central cavity, an

annular coloured portion, and a thin capsule. The largest has a cavity of the size of a pea, which is surrounded by a dense, striated, reddish, stone-coloured matter, of about one-eighth of an inch thick; and the other is smaller, and the coloured ring, which is of about the same thickness, is of a bright yellow or orange colour, and is lined by an opaque white membrane, resembling the corpora albida of this paper.

10. A preparation belonging to Dr. Paterson, Professor of Midwifery, Anderson's Institution. A dropsical woman, who died of apoplexy in ninth month of pregnancy.

Ovaries large, and circumference of each copiously studded within and in the peritoneal coat with small-sized vesicles. Cicatrices nearly effaced from exterior. In one of the glands there was nothing else observable, but in the other there was an extremely white, convoluted, elliptical body, without a cavity, being the remains of a thin, brainy cyst, bleached by long maceration; and adjoining it was a globular body of the size of a recent marrow-fat pea, which had been divided through its centre, and which consisted of a cavity as large as a dried pea, lined by an extremely dense white membrane, and surrounded by a ring of light fawn-coloured matter, the periphery of which seemed circumscribed by imperfect traces of an investing capsule.

On more careful examination, the existence of such an investiture could not, however, be demonstrated; and the annular portion, which was of about the thickness of sheep-skin, presented an obscure linear, and, in some parts of its outer margin, a very well-marked brainy or convoluted appearance; and the internal lining or cyst was seen to have its general surface slightly furrowed and scabrous, as if from corrugation. This latter portion was easily separated, at its cut margin, from the exterior fawn-coloured or granular substance, and, on lifting it up, was found to consist of a very firm tenacious tissue, identical with that of the "dense white bodies" of these descriptions, and to have interposed between it and the fawn-coloured ring another, but much more delicate, although a very distinct and beautiful, layer, which could also be raised from the granular matter on which it lay.

11. A girl, aged 24. In latter end of ninth month of first pregnancy. Died, undelivered, of extensive chronic disease, and discharge of blood from stomach and bowels. Placenta attached to left cornu.

Right ovary somewhat lengthened and narrowed; external surface smooth; internal exhibited one white body, and numerous small vesicles, many of which were near the circumference, some elevated above it, one or two of which, as if recently discharged, left minute superficial openings.

Left ovary.—Periphery smooth, and free from cicatrices, with the exception of a number of elevations of small vesicles, and one or two capillary-sized shallow openings. On uterine end of gland was a tumor as large as a small raisin, of firm contexture, and having two varicose tortuous vessels, filled with dark blood, traversing it externally, and a small foramen in its centre. On cutting this in two, its segments were found of a kidney shape, their circumference consisting of a fibrous tissue having its fibres running obliquely across, and of a pale slightly yellowish colour, which, on exposure to the air, became redder, and assumed something of a fleshy or pale muscular look. The transverse diameter of this ring was about an eighth of an inch; its inner surfaces were separated merely by a curved sulcus, lined at its bottom by an opaque pellicle, which presented the appearance of a white streak, bisecting the more central portion of the body in the direction of its length.

11 A. Preparation 43 R. R., Glasgow Hunterian Museum.

Ovarium with a portion of gravid uterus adhering. The tube is distended with spirits, and is larger at the end next ovarium than the barrel of a writing pen. Ovarium slit open shews a body of size of a hazel nut, with a cavity nearly as large, formed by an opaque, white, dense looking membrane, which is surrounded by a ring of shining, yellowish coloured, granular matter, of considerable consistence. Through the kindness of Professor William Thomson, the preparation was removed from the spirits and examined, when, at a point in the cut edge of the smaller segment of the ovarian cyst nearest to the surface of the ovary, the membranous body forming the walls of the cavity was found to consist of an internal

thick, dense, white layer, lying on a distinct and well developed, more external, but much thinner coat, on the outside of which the solid granular matter was seen to be deposited.

11 B. Preparation 176 R. R., Glasgow Hunterian Museum.

A section of uterus and placenta adhering. The cells of the placenta injected red from the vessels of the uterus. Ovary contains a body surrounded by a ring of injected vessels, and of size of a large garden pea, which is formed of a quantity of extremely solid and beautiful yellow granular substance, enclosing a compressed angular-shaped material of about the size of a grain of wheat, having the colour, consistence, and appearance, of one of the white bodies of the ovary, occupying the cavity of the cyst, and squeezed together by the growth of the external granular tissue. None of the blood-vessels of the yellow substance penetrate the body, which, although in close mechanical apposition with its adventitious covering, and having one or two delicate processes shooting into its structure, and on these accounts is so firmly wedged as not to admit of being separated with any moderate force, is yet not organically connected with it.

[To be continued.]

CAUSES OF THE HIGH RATE OF MORTALITY IN LIVERPOOL.

"We must take great pains to shut our eyes upon truth. There is a radiance about it that makes the outline of its form perceptible, even amongst the clouds of dust and rubbish that are sometimes heaped upon it."

Three Experiments of Living.

To the Editor of the Medical Gazette.

SIR,

IN a paper which appeared in the MEDICAL GAZETTE of 29th December last, "On the Average Number of Deaths in Capital Operations," Mr. Halton introduces a critique on my pamphlet "On the Physical Causes of the High Rate of Mortality in Liverpool;" and he speaks in terms of disparagement of my evidence before the House of Commons' Committee on the Health of Towns, intimating his concurrence in the opinion that it is a

"foul and unmerited libel on the town."

I beg permission to call the attention of your readers to the singular inconsequence of reasoning which pervades Mr. Halton's criticism.

It will be convenient, in the first place, that I should explain what he means by the following charge, which he makes at page 398, and which is somewhat vaguely expressed, viz. "That the conclusions which are drawn with respect to the general healthiness of the town are borne out even by his own tables, I must object." Here he does not specify the conclusions to which he objects, but from communications which I have had with him since the publication of his paper, I find that they are the following, viz. (p. 7,) "That, judging from the annual proportion of deaths to the population, Liverpool is the most unhealthy town in England;" which he thinks at variance with the admission (p. 60), that there is a district in Liverpool (Rodney Street and Abercromby Wards), containing upwards of 30,000 inhabitants, in which "the mortality is below that of Birmingham, the most favoured in this respect of the large towns of England;" while he thinks this admission inconsistent with the assertion (p. 62), "that the influence of these seats of pestilence is not confined to those who reside within their immediate limits, but extends itself to the whole town, poisoning the atmosphere which all classes are compelled to breathe," &c.

I also learn from Mr. Halton, that he knows nothing of my evidence before the Committee of the House of Commons, more than what my pamphlet discloses.

We are now prepared to discuss the subject.

First, as to my evidence before the Parliamentary Committee. The terms in which Mr. Halton mentioned it, led me to suspect, at once, that he had never read it; because I did not believe that any "thinking" man who had read it could join in the absurd outcry about its being "a foul and unmerited libel on the town." It now appears that my suspicion was well founded. Mr. Halton says, "I know nothing of the evidence more than what your pamphlet discloses." Now, my pamphlet discloses absolutely nothing as to

the nature of the evidence, beyond the fact, that it related to "the prevalence of disease among the working classes, and the high rate of mortality in Liverpool," and that it was "a mere statement of facts,"* But this is quite sufficient to decide him. He seems to have thought it impossible that I could open my mouth on such a subject without uttering a foul libel on the town; and he does not hesitate to pronounce judgment accordingly; either forgetting, in his haste to condemn me, or acting in defiance of the fact, that he knew nothing whatever of the nature of the statements he so unceremoniously stigmatised. Was this fair? Is it a specimen of the "close and consistent reasoning of a thinking man?"† Would it have been too much to expect that he should have made himself acquainted with the evidence before consenting to utter and to circulate such a "foul libel" upon it and upon myself?

I wish I could say that this were the only instance of apparent haste and want of care presented by Mr. Halton's paper. But I have a still more serious charge, if possible, to bring against him. I complain of his having entirely misrepresented the scope and object of my pamphlet—so completely and thoroughly misrepresented it, as infallibly to mislead all who have not read it, and thus had an opportunity of judging for themselves. From the general tenor of his observations, it would be supposed that I had attempted to connect the high rate of mortality with some defect in the locality of the town, or with some natural insalubrity of the atmosphere, which it would be of course beyond our power to remedy. Now, would any one, who took his impression solely from Mr. Halton's critique, believe, that the whole aim and object of my evidence before the House of Commons' Committee, of my Report to the Poor Law Commissioners, and of my paper "On the Physical Causes of the High Rate of Mortality in Liverpool," was to show that the high ratio of deaths was due in a great measure to the "vicious construction of the dwellings of the working classes, the insufficient supply

* *Physical Causes, &c.* p. 7; the only passage where my evidence is referred to.

† Mr. Halton's Paper, *MEDICAL GAZETTE*, p. 298.

of out-offices, and the absence of drains, the deficient sewerage, and the overcrowding of the population;"* these evils existing more prominently in some districts of the town than in others, but all of them susceptible of remedy to a greater or less extent, and that not a word is said of any natural insalubrity in the air, or in the locality of the town? but, on the contrary, that some of the natural advantages of the locality are expressly pointed out, and attention called to the comparatively low rate of mortality prevailing in the outskirts? Mr. Halton says, "the conclusion at which I arrive, after a perusal of the tables, is, that we are not to infer that the locality of Liverpool is unhealthy, but that"—what? some conclusion of course very different from mine?—"the atmosphere in particular districts of the town is very much deteriorated by the construction of the dwellings, the close manner in which the inmates are packed, and the filthy habits of the population," &c.; the very conclusions at which I had arrived, but which he presents to his readers as peculiar to himself, and at variance with the opinion which I entertained! Mr. Halton is the first, so far as I know, who has put this extraordinary interpretation on the pamphlet. Since its publication, I have received communications on the subject, from many medical men, and others, in different parts of the kingdom: it has been commented upon by all the local prints, and by several medical and other periodicals; and in no one instance has any other interpretation been put upon the pamphlet than that which it was intended to bear. I cannot ascribe his strange interpretation, therefore, to anything but undue haste in reading over the pamphlet, and possibly a desire to skim quickly over a rather dry subject.

After quoting, from page 62, a passage with reference to the mortality of Rodney Street, and Abercromby, as compared with that of Vauxhall and Exchange wards, he says, "Does this refute the statements of Dr. Dobson, Mr. Moss, and the Liverpool Medical Journal, as quoted by himself, and which he sets off with, resolved to overturn?" Mr. Halton will probably be surprised to learn that this was not

the object of the passage which he quotes. Nothing was further from my mind than Dr. Dobson, Mr. Moss, and the Liverpool Medical Journal, when that passage was penned. Its object was entirely different. It was intended to show that, by sanatory measures properly applied, there was every reason to believe that the mortality of Vauxhall and Exchange wards might be more nearly approximated to that of Rodney Street and Abercromby wards than it now unfortunately is. But neither does it "confirm the printed records of the health of the town" (where they are to be found I know not); for if the mortality of Rodney Street and Abercromby wards be low, that of Vauxhall and Exchange wards is more than sufficient to give a high aggregate average to both districts; and Mr. H. leaves entirely out of sight the fact, that in every other district of Liverpool the mortality is high, although not so high as in Vauxhall ward.

The merit of refuting the "prevalent impression," that, "as compared with other large towns, Liverpool occupied a favourable place in the scale of mortality," is not due to me, nor was that the object of my pamphlet. That impression had been already effectually refuted by the short and simple story of the Registrar-general. His returns had proved that a greater number of deaths occurred in Liverpool, "in proportion to the number of the inhabitants," than in any other town in the kingdom; and my purpose in writing the paper which the Literary and Philosophical Society printed, was to offer an explanation of this—not, alas! "prevalent impression"—but ascertained fact. In preparing the paper, I succeeded, with some labour, in eliciting from returns furnished to me by the superintendent-registrar the various rates of mortality in the different districts of the town; and I endeavoured to trace a connection between the rate of mortality and the greater or less prevalence of physical remedial defects in the different wards of the parish. If any one point was made more prominent than another, in my pamphlet, it was this varying rate of mortality in different districts; it was my *great* point—the one of chief importance to my argument. And yet this very fact, which was made public for the first time in

* Physical Causes, &c. p. 20.

my pamphlet, Mr. Halton accuses me of wishing to conceal, or, at least, to make of secondary importance. The very passages he quotes, from pages 60 and 62, might have suggested to him that he had misapprehended my argument.

He objects to the *title* of my paper, for which he would substitute, "On the physical causes of the high rate of mortality in *particular districts* of Liverpool," which, he says, is all that has been proved. He can scarcely require to be informed that the rate of mortality in any town is ascertained by dividing the number of inhabitants by the annual number of deaths. This being done, for instance, in the case of Birmingham, London, Bristol, Manchester, and Liverpool, the rate of mortality in

London is said to be . . .	1 in 37½
Birmingham	1 in 36½
Bristol	1 in 32½
Manchester	1 in 29½
Liverpool	1 in 28¾

And, this being the result, all statisticians agree that, in Liverpool, the "rate of mortality" is high; the existence of one healthy district in a town not being considered sufficient to justify any departure from this rule of nomenclature, unless the deaths in that district were so few, in proportion to its inhabitants, as to give a low aggregate mortality to the entire town. But how is the fact with regard to Liverpool? Why, that even after giving the town generally the benefit of the low rate of mortality in Rodney Street and Abercromby wards, the general average, *i. e.* the "rate of mortality in Liverpool," is higher than in any town in England. In two wards, containing about 3,000 inhabitants, the mortality is low; but in the remaining *ten* wards of the parish, containing 200,000 inhabitants, it is high. The question is, are the two wards with 30,000 inhabitants, or the ten wards with 200,000 inhabitants, to give their character to the town? If, in a court containing twelve houses, two houses were healthy, and the remaining ten unhealthy, should we not be justified in saying that it was an unhealthy court? Or, if 200 out of 230 houses in a street were notoriously unhealthy, would not that be properly called an unhealthy street?

It will thus be seen that the assertion that, "judging from the annual pro-

portion of deaths to the population, Liverpool is the most unhealthy town in England," is not, as Mr. H. supposes, at variance with the admission that the mortality of Rodney Street and Abercromby wards is low; but that the two statements are perfectly in unison. Nor is there, as he imagines, any discrepancy between this admission and the statement (page 62) "that the influence of these seats of pestilence is not confined to those who reside within their immediate limits, but extends itself to the whole town, poisoning the atmosphere which all classes are compelled to breathe," &c. I had supposed that the meaning of this was sufficiently obvious, viz. that while the influence of these seats of pestilence is *chiefly* exerted within their immediate limits, it is not altogether *confined* to those limits; and the evidence in support of this assertion was given in the shape of a table, constructed from Mr. Chadwick's Sanitary Report, which shewed that the average age, at death, even of the highest classes—those who abound most in Rodney Street and Abercromby wards—was lower in Liverpool than in any town where the calculation had been made, excepting Bolton (whose general average, however, is two years higher); the average age, at death, of the gentry in Bath, being 55; in Kendal, 45; in four metropolitan unions, 44; in Leeds, 44; in Manchester, 38; and in Liverpool, only 35. This difference in the average age, at death, (which is admitted to be a better test of the healthiness of a district than even its proportionate mortality)* must have some

* I extract the following from Mr. Chadwick's "Supplementary Sanitary Report," just published. "Wherever the presence of the causes of death has yet been observed to be very great, there the line of mortality, or the average age of death, is below what may be called the line of vitality, constituted by the average age of the living; and wherever there is, on the whole, any diminution of those causes of death, as by better ventilation, or by widening streets, opening new thoroughfares, better supplies of water, sewerage and cleansing, and improvements in the general habits of the population, there the line of mortality, the infantile mortality especially, diminishes; the average age of each adult class, up to sexagenarians or octogenarians, increases, and the average age of death ascends above the average age of the living. * * * In Liverpool—where the investigations into the condition of the resident cellar population certainly shew an increase of the causes of death—overcrowding, defective ventilation, bad supplies of water, and increased filth—the average age of death is, for the whole town, 17 or 18 years only; whilst the average age of the living population, so far as it can be made out from the mode in which the census is prepared, is 24 years." (pp. 245-6.)

cause. The cause which I suggested may not be the true one; and yet it is desirable that it should prove so, because it is one that is susceptible of remedy; and Mr. Halton does not even attempt to prove that it is not the true one. All that is meant, therefore, by the statement at page 62, which he thinks inconsistent with the admission of the low rate of mortality in Rodney Street and Abereromby wards, is, that low as is that rate, it might probably be still further reduced by sanitary measures applied to the other districts of the town.

Mr. Halton can hardly have been serious in supposing that his appeal to his individual experience of the longevity of natives would be allowed to outweigh the accumulated experience of every individual in Liverpool, or that because he happens to be acquainted with two gentlemen upwards of eighty years of age, he is justified in denouncing the publication of officially authenticated facts as libellous, or "most unfair." Were I acquainted with a dozen natives of Liverpool upwards of eighty years of age, I should never dream that this could justify me in denying the statement of the Registrar-General, who tells us that a smaller proportion of the inhabitants reach the age of seventy in Liverpool than in any other town in England. Any one who trusts to his individual experience in such cases, trusts to a "vague impression," which is sure to mislead him. Besides, Mr. H. does not mention the "particular district" of Liverpool in which his octogenarian friends reside. Should it turn out that their residence (if in the parish at all) is within the favoured limits of Rodney Street, or Abereromby Wards, then a whole regiment of such octogenarians would, on his own showing, prove nothing as to the "general healthiness of the town." But let him tell me that he knows two such individuals who were born, and have passed their lives, in a filthy court or cellar in one of the other "particular districts" of the town, and I will at once admit that it is a circumstance worthy of record.

Mr. H. proceeds as follows:—"But that the general health of Liverpool is to be denounced because the general bill of mortality is swollen with the deaths of such poor who come here with already impaired constitutions

and inherent maladies*, to be developed by a residence in the particular districts described, is most unfair. It is 'a foul and unmerited libel on the town.'" Now, setting aside the fact that he here begs the question, offering no shadow of proof of what he advances, Mr. H. admits that the general bill of mortality is swollen by deaths caused by inherent maladies, which are developed by a residence in the particular districts described; *i. e.* in badly sewered districts, abounding with filthy, ill-ventilated courts, and dark, damp, noxious cellars. Why, this is very nearly what I myself assert, and I ask, is it really "most unfair" to lay these deaths at the door of the town which cherishes such very "particular districts" within its bosom? I assert, that it is *not* unfair, that it is *not* a libel on the town. It is truth; plain, straightforward, melancholy, but wholesome *truth*. How his statement that it is a libel on the town to charge it with the deaths induced by a residence in these "particular districts," is to be reconciled with the paragraph which follows, where he admits that this great mortality is a "monster-evil, demanding the prompt interference of the local

* "As formerly, when navy surgeons, overlooking the filth of their ships, which has since been removed, and not perceiving the effects of the atmospheric impurities arising from the over-crowding which have since been diminished by better ventilation, directed their whole attention to supposed distant causes and mysterious agencies, and were wont to ascribe the whole of the fever which ravages a fleet to infection from some casual hand, who was found to have been received on board from some equally filthy and ill-kept prison, where the gaol-fever had been prevalent; so now, in some of our towns, we find much ingenuity exercised to avoid the immediate force of the facts presented by such returns, by a search for collateral and incidental defects in them. Thus, in Liverpool, the whole of its vast excess of mortality has been charged upon the poorer passengers who pass through the port. In other towns also a like excess of deaths from epidemic or infectious disease is charged upon the vagrant population. In New York, and some of the American cities, a common observation made on the proved excess of mortality is, that a large proportion of "foreigners" frequent the city. An inquiry into the cases themselves would generally show that the proportion per cent. of sickness and mortality from consumption and other diseases, amongst the *resident* population, is the greatest; and that even in lodging-houses the disease most frequently appears first in the occupants who are stationary, and last in the new comers. In so far as the general results of mortuary registration of any district are disturbed by a population who are migratory, they are usually disturbed by unduly raising and giving the locality an appearance of an average of health, and the fatally deceptive chances of longevity, that do not belong to it.—*Supplementary Sanitary Report*, pp. 243-4.

authorities," and calls upon the corporation to prove themselves conservators of the public health," to apply a "zeal and energy" to the subject, and not to let "the plea of a want of funds stop the good undertaking," I leave it to himself to decide. To me they appear to be irreconcilable.

One word more with regard to his doctrine of "particular districts," on which he lays so much stress, and which, indeed, is the *ignis fatuus* which has led him astray. Suppose a party of twelve individuals wandering along the sea-shore, and overtaken by the advancing tide, ten of their number were cut off, while two only succeed in gaining a place of safety on a rock, high and dry above the raging waters. The ten unfortunate members of the party call aloud to the spectators on the shore for help. "We are drowning! We are drowning!" What would be thought of the conduct of the two perched upon the rock, who should say to the ten struggling wretches beneath them, "Silence! don't alarm our friends on the shore; they will think we are all drowning, but you know we have gained a place of safety; and, turning to the spectators, should cry out, "Don't make yourselves uneasy on our account; it is a mistake; we are *not* drowning; here we are, you see, safe and sound." And then, *sotto voce*, "It is true, that immediately around the rock are ten 'particular' deep holes, which have engulfed ten of our number, but that is no reason why such an outcry should be made while two of us are safe. It might excite threatening in the minds of our friends, and "operate to the disadvantage" of our characters as cautious and prudent men, if it were known that we had exposed ourselves and our friends to such a danger." I ask, what would be thought of conduct such as this, which, from a morbid and misplaced feeling of regard for their character and individual interests, should induce men to peril the lives of so many of their fellow-creatures? The comparison may be exaggerated, but can hardly be called unfair; for mischiefs which accrue in consequence of an obstinate refusal to open the ears when the presence of danger is announced, entail a nearly equal responsibility with those which are wilfully and deliberately incurred. "Error does not so often

arise from ignorance of truth, as from unwillingness to receive it." I do not exactly say "*mutato nomine*," &c. for I cannot doubt that Mr. Halton, equally with myself, has the real good of the community at heart, and that we differ only in the steps by which we think it desirable to accomplish that object. He seems to think that the less that is said about it the better, while I believe that a knowledge of the evil is the first necessary preliminary to its cure: and that could he succeed in his wish to do away with the "fancy" which he says is now "abroad against the health of the town," he would be the unconscious author of a calamity which, when its results became apparent, he would probably be the first to deplore. It is a *wholesome* "fancy," and one which I am sure the "reasoning of thinking men," however "close and consistent" it may be, will never "dispel," if the steps which are now taking to remedy the evil should unfortunately be interfered with. I may fairly retort upon him his own expression in castigating another unfortunate victim of his wrath, "What! in the face of such frightful mortality as is represented, are we to exercise any reserve?"

I must be allowed to say something on behalf of the Literary and Philosophical Society, to whom, also, he extends the benefit of his lash. "Does it speak much for the acumen of the Liverpool Literary and Philosophical Society, who have published the pamphlet? Ought they not to have been the guardians of the character and interests of Liverpool, and not have been the means of circulating what has operated unjustly to the disadvantage of the town?" I think it *does* say much for their acumen, and redounds very much to their credit, that, embracing, as the Society does, men of every party, and every shade of opinion, they resolved unanimously—regardless of private interest, and of party feeling—to publish, at their own expense, what they believed would operate to the advantage of the community of which they are members. And in doing so, they have met with their reward. They have seen the dormant energies of the Commissioners of Sewers awakened to new life and activity, steps taken for the immediate shutting up of inhabited cellars in courts, notices given for the vacating of other cellars which are

unfit for human habitations, and the other clauses of the "Act for the Promotion of the Health of the Inhabitants of Liverpool," carried out with a vigilance previously unknown. Are these things to the "disadvantage of the town?" If they are not, I assert that the Literary and Philosophical Society has proved itself to be the *true* "guardian of the character and interests of Liverpool."—I am sir.

Your obedient servant,

W. H. DUNCAN, M.D.

Physician to the Liverpool Infirmary,
and Consulting Physician to
the Dispensaries.

P.S.—Should Mr. Halton desire further confirmation of my statements regarding the high rate of mortality in Liverpool, I beg to refer him to the remarks of the Registrar-General in his Fifth Annual Report, just published; pp. xxiv.-v.; to the tables, pp. xxv.-xxvii. and xxxiv.; and especially to the diagrams, pp. xxxvii.-viii.; shewing the comparative value of life in Surrey, Liverpool, and the metropolis.

ON THE RESULTS OF AMPUTATIONS.

To the Editor of the Medical Gazette.

SIR,

A DECEMBER number of your journal contains a paper from Mr. Halton, of Liverpool, in reference to the mortality attendant upon the great operations of surgery. With his opinions on the subject I have no desire to interfere, but as he has done me the honour to refer to me several times in the course of his communication, it might appear, were I quite silent, that I acquiesced in the correctness of the conclusions he has drawn, though they are in many respects different from my own.

In 1837, I presented to the Royal Med. and Chirurgical Society, a paper on the Results of Amputation, in which it was shewn that the mortality was between 20 and 30 per cent. Mr. Halton thought that paper overstated the risk, and gave his own personal experience in proof that his opinion was correct. So far as his statement goes it shews that the results of operations in his hands have been favourable, but he has not given us the means of making any comparison between the success of his practice and

that of other hospital surgeons: for this purpose the actual number treated should be given.

Mr. Halton gives us the results of his own operations, without stating the number of cases: thus, his mortality after amputation of the thigh is one in eleven, and no doubt it is favourable; but he well knows that he might throw up a penny and it might come heads ten times following, though the chances of its coming tails were equal, and that if he threw it up a hundred times no such inequality would exist. If in the course of his practice he should amputate the thigh a hundred times, I greatly fear he will lose more than nine patients. I have known a surgeon who cut twenty patients for stone, with only two deaths; but in the next twenty he lost six. I have heard of a very dexterous surgeon who lost seven cases of strangulated hernia in succession. And even in the Glasgow Infirmary, where the mortality is large, of the first 30 amputations attended to by Mr. Lawrie, 29 patients recovered, the operation being the circular. Of the last 30 the deaths were 8, and of a middle 30, the deaths were 11, though the flap operation was performed.

There is one paragraph in Mr. Halton's paper which clearly shews the force of the preceding remarks: he says, "In the lateral operations on the bladder, with a view to remove foreign body or stone, and the operations for applying ligatures on large arteries, in popliteal and subclavian arteries, I have merely to observe, that I have several times operated for aneurism including the subclavian, and for the removal of stone or foreign body from the bladder by the lateral operation, *but have no death to record.*" Is it intended that we should infer that he has tied the subclavian several times, and cut into the bladder many times, without loss? If so, why not say so? Because, as the passage stands, it might also be inferred that he has tied the subclavian once, and cut for stone three times, without loss, and there would be nothing very unusual in such a result.

Mr. Halton cannot acquiesce in the feeling which led me to determine to withhold the names of several hospitals included in the returns made to me, "because in certain hospitals the mortality after amputation had exceeded fifty-three per cent. whilst in several

it had not exceeded twelve per cent., and in one of the number, out of twenty amputations there was only one fatal result."

If I wanted any proof that I took a prudent course in withholding the names, I should find it in the fact, that in the hospital where the mortality was then represented by one in twenty, it is now represented by four in twenty; and in that in which the mortality was fifty-three per cent., it is now thirty-one per cent. Mr. Halton does not seem to have sufficiently considered the true value of figures, in which large numbers are necessary to dissipate errors.

Mr. Halton is dissatisfied with my reference to the extraction of ovarian cysts, and particularly with the following passage, "that an operation which under adverse circumstances has succeeded nine times in twelve cases ought to be resorted to." "We do not hesitate to have recourse to the ligature of large arteries, and regard it as a justifiable operation, though the results are less favourable; we do not object to perform amputation of the thigh, although nearly two out of five patients die;" and notwithstanding Mr. Halton's dissent, I apprehend the opinion I have expressed is correct. I have assisted at the extraction of five ovarian cysts, and four of the patients are alive, and I intend to shew in the sequel that I am not far wrong in my estimate of the results of amputation of the thigh.

It is a source of much satisfaction to me to reflect that I sought, nearly seven years ago, to direct the attention of the profession, more strongly than had previously been done, to the mortality attendant upon the performance of the great operations of surgery; and I am rejoiced to find that, ere long, we shall be in a condition to form a reasonable estimate of the risk in each case. My paper, which was read before the Royal Medical and Chirurgical Society, had reference to amputation; and the results were so unexpected in some quarters that the Council declined to publish it in their Transactions, believing, as they did, that some errors had crept into my tables, and had thus exaggerated the actual risk. Several years have since passed away, and several returns have been since made, among which, that of Mr. Lawrie, in reference to the results of amputation in the Glasgow Infirmary, is the most

comprehensive and complete. Those returns go far to show that my communication at least did not overstate the loss of life after amputation. Few surgeons to whom the habit of enumeration is familiar, now dispute the substantial correctness of the estimate I then made. With some of the results then given I am not now satisfied; and I hope to be able to shew how far they are modified by the affected limb, as well as by the disease, or the injury, which has rendered the operation necessary. The means at present at my disposal to accomplish this object are not satisfactory: they are the whole, so far as I know, of the cases of amputation recorded in the periodical literature of this and other countries during the present century, amounting to 1369 cases, exclusive of those contained in my former paper, those in the practice of military surgeons, those of Lawrie, those of the Northern Hospital, Liverpool, and those of the Hôtel Dieu at Paris. I by no means think that the results furnished by such data will fairly represent the mortality. I believe it will be understated, because successful cases are more likely than unsuccessful ones to find their way into print. Such as they are I will now state them; and I may take another opportunity of giving the results of the operation for strangulated hernia, taken from the same sources. The results of the ligature of arteries were published in Mr. Arnott's Hunterian Oration.

Cases in which amputation was performed for the immediate relief of injuries.

	Cases.	Deaths.	
Thigh .	245	176	or 72 per cent.
Leg .	204	88	or 43 per cent.
Arm .	164	49	or 29 per cent.
	613	313	or *51 per cent.

Cases in which amputation was performed for more or less chronic diseases.

	Cases.	Deaths.	
Thigh .	415	87	or 21 per cent.
Leg .	231	61	or 27 per cent.
Arm .	110	26	or 24 per cent.
	756	174	or 23 per cent.

The Glasgow returns are as follows,

* Taking an equal number of operations in each limb.

from 1794 to 1838:—276 amputations, 100 deaths, or 36 per cent.

A further analysis shews the following results:—

Amputations for injuries.

	Cases.	Deaths.	
Thigh . . .	36	27	or 75 per cent.
Leg . . .	27	18	or 67 per cent.
Arm & forearm	58	20	or 34 per cent.
	121	65	or 54 per cent.

Amputations for disease.

	Cases.	Deaths.	
Thigh . . .	92	19	or 21 per cent.
Leg . . .	35	12	or 34 per cent.
Arm & forearm	23	4	or 18 per cent.
	150	35	or 24 per cent.

The results of amputation at the Hotel Dieu, between 1st of Jan. 1836, and the 1st of Jan. 1842, according to Malgaigne, are—

For the relief of injuries.

	Cases.	Deaths.	
Thigh . . .	46	34	or 74 per cent.
Leg . . .	79	50	or 63 per cent.
Arm . . .	58	25	or 43 per cent.
	183	109	or *60 per cent.

Cases in which amputation was performed for more or less chronic diseases.

	Cases.	Deaths.	
Thigh . . .	153	92	or 60 per cent.
Leg . . .	113	55	or 48 per cent.
Arm . . .	78	29	or 37 per cent.
	344	176	or 51 per cent.

A comparison of the results obtained from the sources I have named with those of the Hôtel Dieu, leaves a dark shade upon the practice of that hospital, the general results after injuries shewing a mortality of 51 per cent. in the one case, and 60 per cent in the other. For the removal of a diseased limb the probabilities of success after operation are still more unfavourable. In the former case they are represented by 23 per cent., in the latter, 51 per cent.

I believe, however, that our periodical literature does not fairly represent the results. I believe that the number of unsuccessful cases reported is no fair representation of their proportion to

those which are successful. In relating or publishing the results of individual practice in established operations, it is hardly to be expected that a man will publish that he has been very unsuccessful, and therefore it is only the bright side of the picture that is exhibited. Where the archives of an hospital are ransacked, as was done for the Hôtel Dieu, and the Glasgow Infirmary, the successful and the unsuccessful results are equally dragged into the light. Large as the mortality at the Hôtel Dieu may appear, especially in amputation for disease, it is less striking when compared with Dr. Lawrie's returns of the mortality of the Glasgow Infirmary after injuries; the mortality in the former institution, taking an equal number of each limb, was—after injuries, 60 per cent., while at Glasgow, the proportion was 54 per cent.

If we add together the number of cases of amputations of the thigh furnished by the preceding returns, they amount to 987 cases, and 435 deaths, or 44 per cent. ! My former statement, of 2 out of 5, was, therefore, no exaggeration, in so far as regards the thigh. If we take the Hôtel Dieu and Glasgow returns, it is under the truth.

With reference to such injuries of the limb as make immediate amputation of the thigh necessary, every surgeon will be prepared to confirm the gravity of the risk shewn by the return. It is obvious that where the amputation is called for by serious accidents, the injuries are frequently not confined to the limb; and this circumstance goes to some extent in explanation of the much more unfavourable results in such cases than in those where the operation was performed by reason of chronic disease.

There is one curious result; the smaller mortality in chronic cases when the amputation was performed above than below the knee: this fact is observable in Mr. Halton's return, as well as in those of the Hôtel Dieu at Lyons, during the surgeoncy of M. Janson, and in those of Dr. Lawrie. Another point, which cannot fail to impress itself on the mind, is the necessity of great caution in judging of results. If we assume the returns I have given to be correct, it must be obvious that the results should bear a direct relation, not to the number of operations, but to the nature of the

* Taking an equal number of each limb.

cases requiring operation. Suppose the case of two hospitals, one in a rural district, in which operations for injuries were rare, the other in a manufacturing town, where accidents from machinery were frequent. In the one case the mortality might not exceed 25 per cent., in the other it might not be under 50 per cent., and the surgeons might be equally able in each.

Mr. Halton refers to the large mortality of the Northern Hospital at Liverpool as compared with the Infirmary: how far would the reasoning I have used apply in this case? He states himself that the Northern Hospital was established as a convenience to those who suffered from accidents at the docks, the Infirmary being a mile off. Is it, then, a fact that a large portion of the cases taken to the Northern Hospital are severe injuries, many requiring amputation? If it be, the explanation of the difference in the mortality may be as satisfactorily given as by assuming that it is owing to the situation, the want of cleanliness, insufficient ventilation, or want of skill in the medical officers.

After the preceding observations had been written, I read a letter from the surgeons of the Northern Hospital in answer to Mr. Halton. Some of their explanations are similar to my own; but as I know nothing of the practice of either hospital beyond what is stated in their papers, my remarks can only have a very general application.

I am, sir, faithfully yours,
B. PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary,
Assistant-Surgeon to the Westminster Hospital.

HYDROPATHIC TREATMENT OF GOUT—FUNGOID DISEASE OF UTERUS.

To the Editor of the Medical Gazette.

SIR,

THE lamented death of Sir Francis Burdett brings to my mind a similar occurrence in my own practice, which with your leave I will relate.

On the 17th of January, 1835, Mr. H. Stephen, an officer of the Customs at this port, sent for me to prescribe for a swelling of the left foot and ankle, which he attributed to a slip or sprain: as he felt and looked well in other respects, it did not occur to me to ask

any questions, and I contented myself with ordering a few leeches, to be followed by a cold lotion constantly applied. At midnight, I was summoned to him in great alarm, and found him coughing up, every moment, mouthfuls of fluid and frothy blood: he breathed with difficulty and great anxiety, with a rattling noise in the windpipe; the swelling and pain of the foot were quite gone. He was bled twice that day, and treated with antimonials, &c. and to my great surprise, on the third morning of my attendance, I found that all the pulmonary symptoms had vanished, and in lieu thereof the right foot was swollen and very painful; "*Gare l'eau*" became our motto, and the foot was let alone. It was his first attack of the kind, and in all subsequent ones you may rest assured that the hydropathic plan was not the one adopted. We have had no more hæmorrhage from the lungs.

Now, sir, my object in the above narrative is not to deery any particular system, but to warn the more zealous and conscientious votaries of hydropathy of the danger of repelling gout in certain constitutions: 'tis not enough for them to urge the example of physicians who have fearlessly plunged their gouty feet into cold water with the most perfect relief; facts are stubborn things. The fate of the worthy Baronet, and the incident now adduced, cannot be gainsayed. Your poor man is in no danger of having his gout repelled; 'tis your credulous rich, who are invited to these fountains of health. The cunning dogs care not for the sores of Lazarus, but are ready enough for a consideration to furnish Dives with water to his heart's content.

I further beg leave to offer the two following cases of malignant disease of the os uteri complicated with pregnancy, to which I would especially invite the attention of Dr. Lever, who has lately published an excellent little work on diseases of the uterus. Fungoid disease of the os uteri I am inclined to think is very rare, as I have not found, upon inquiry amongst our practitioners of most extensive experience, that they have met with it in this very populous district.

CASE. I.—Mrs. W. H., about 28 years of age, the mother of three children, of a fair and florid complexion and strumous constitution,

sent for me in October 1835, having flooded very much—to fainting. She was six months gone in her fourth pregnancy. Upon examination per vaginam no trace of the os could be felt, but in its place a large spongy mass of the consistence of liver, that broke down under moderate pressure of the finger. A slight pain or two made this substance split open in a radiated form; and then the head of the fetus could be felt through the membranes. In consultation with a practitioner of great experience in this town, it was determined to draw off the liquor amnii, and bring on speedy labour, by way of obviating the recurrence of fresh hæmorrhage, which she was now unable to sustain without extreme danger. The next day the *fortus* was expelled, driving before it a substance as large as a cricket ball. This woman died about six weeks after from exhaustion and fever; and upon opening the body the uterus was found to be nearly reduced to its ordinary size, and was healthy in its structure, except at the margin of the os, which was thick and circular, of the diameter of a half-crown piece, from whence a fresh excrescence was coming forth, of a grey colour, and very much resembling, in texture, colour, and appearance, the structure of an oyster.

CASE II.—Mrs. Bateman, aged 30, a stout-made woman, but having a pasty, unhealthy complexion, was taken in labour at her full time of pregnancy. She had borne children before; had not suffered from any kind of discharge except a thin straw-coloured one during the last two or three months. An examination revealed a large tumor filling the upper part of the vagina, which broke down under the finger. In the course of half an hour the pains pushed forth the membranes, and thereby split up the tumor, portions of which, as the labour proceeded, were expelled, and when the vertex passed through the os uteri the whole mass was cut clean off, and pushed forth before the child. The labour was quite natural; the child was both fine and healthy, and is now living, for aught I know to the contrary. No unusual discharge occurred, and the woman recovered so far as to leave her bed and go about. I presented one of the portions of the

tumor that were cast off to my friend Mr. Hardy, lecturer on midwifery in this town, who had it preserved in the museum of the Hull Medical School.

This woman, after consulting several physicians, some of whom were sceptical as to the true nature of the case (of which I had distinctly apprised her) died about six months after, with the vagina stuffed with a fresh growth of the same description. The specimen preserved shows the usual brain-like and laminated structure peculiar to malignant disease.

This last case is instructive, as proving that pregnancy (in the absence of dangerous hæmorrhage) may be allowed to proceed to the full term, and justifies the observation made by Dr. Lever, in his very able publication: for in my opinion the disease is limited, during pregnancy, to the os uteri, while the whole apparatus of parturition, which resides in the fundus, remains healthy and intact as long as the *fœtus* remains in utero.

Hoping that the preceding cases will prove interesting to your readers, I remain, sir, your obedient servant,

HENRY C. SHERWIN.

Hull, Feb. 28, 1844.

ON THE
EFFICACY OF PRUSSIC ACID IN
OPACITY OF THE CORNEA, &c.

To the Editor of the Medical Gazette.

SIR,

HAVING at a former period described a case of diseased cornea, treated by the application of the vapour of prussic acid, which was afterwards inserted in the *MEDICAL GAZETTE*, I now deem it proper to state candidly that since then I have applied the vapour again and again to various affections of the eye, according to the ingenious method of Dr. Turnbull, without any bad effect being produced by its action on the eyeball or sight. But, as regards the chief disease or diseases of the eye, to which such a potent remedy is alone suited, it would, I conceive, be a question at present somewhat difficult to solve. However, justice meanwhile compels me to admit, that in no case which has come under my care, where the vapour was by itself applied, have I been so successful as in opacity or disease of the cornea, even although

* Number for January 13, 1843.

most of such were considered hopeless by the unfortunate patients themselves, and friends, on account of the means already used having proved ineffectual for the restoration of their sight.

I shall only give from my note-book a case in point, as follows:—

May 16, 1843.—Thomas Galloway, æt. 23, weaver, of a strumous diathesis. About eight months ago had an attack of inflammation in both eyes, to relieve which went to an hospital, and remained under treatment for about six months, without being benefitted, further than getting rid of the pain and redness. At present both corneæ are occupied with opacities nearly in the centre, and almost covering the whole expanse of the pupil, which renders him unable to read, or follow his usual employment. Had the vapour applied to both eyes daily, for the space of seven weeks; at the end of which, he could read a good type, and was also able to pursue his occupation.

I may state, also, that I have applied the vapour in two cases of amaurosis, along with the ordinary remedies in this disease, with considerable success.

In concluding these brief statements, purely with a view to make known to the profession the results of it in my hands, I cannot forbear expressing a strong belief, that, when cautiously and gradually applied, much good, as has already been done by the vapour of prussic acid in several forms of blindness, will yet be effected, and I doubt not for a moment to find it ere long ranking as a remedy of considerable efficacy in some of the more formidable diseases of the eye.—I am, sir,

Your obedient servant,

G. K. W. PATERSON,

Surgeon, &c.

Perth, March 2, 1844.

CASE OF

CALCULUS IN THE URETHRA.

To the Editor of the Medical Gazette.

SIR,

IF you consider the following case worthy a corner of your valuable journal, I should feel obliged by its insertion.—I am, sir,

Your obedient servant,

JOHN FOSSE HARDING, M.R.C.S.

Spencer Street, Northampton Square,
March 5, 1844.

I was suddenly called, early in the

morning, to J. C., a youth aged 18, as he was suffering from a retention of urine; the bladder not having been relieved of its contents for upwards of twenty-four hours. On attempting to pass the catheter, I discovered that a calculus was impacted in the urethra, just posterior to the glans. As the patient was labouring under the greatest agony from the distension of the bladder, I introduced a small probe to dilate the urethra, which allowed of the urine passing. I then made an effort to extract the stone by means of a long pair of forceps, without success. I therefore made an incision through the glans, when, with the greatest facility, I removed the calculus, which proved to be of the mulberry species, of the shape and appearance of a tamarind-stone, weighing 25 grains. The wound healed readily, and within one week the lad was enabled to return to his vocation, and has since continued in good health, a period of eighteen months, although previously he had suffered from severe acute attacks of hernia humoralis, which were relieved by the usual remedies, but had left a chronic enlargement of the testes; and, in fact, his general health was much impaired. I am of opinion that the calculus had been lodged for some time in the prostatic portion of the urethra, as its shape would lead to suppose, and the symptoms generally, having had great pain in the perineum and rectum; but a remarkable feature in this case is, that at no one period previous to my being sent for had he been inconvenienced from retention, or even any difficulty in passing his water.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégér.”—D'ALEMBERT.

Anatomical Manipulation; or, the Methods of Pursuing Investigations in Comparative Anatomy and Physiology. Also, an Introduction to the Use of the Microscope, &c.: with an Appendix. By A. TULK, M.R.C.S., M.E.S. and ARTHUR HENFREY, A.L.S. M. Mic. S. with illustrative Diagrams. 1844.

WE consider that we do an acceptable and useful service to our readers, in

recording our opinion of the volume the title of which is given above. We have looked through its pages attentively, and have been gratified to find that the work will be of essential benefit to the beginners of the study of comparative anatomy. The execution of the different parts is excellent; and we profess to speak from experience, having ourselves devoted much time to the investigations treated of in the volume, and had occasion to regret the want of such a guide as it affords. We venture to recommend the work strongly, especially to the heads of the medical departments of the navy and army, and to those who superintend the sending out of medical men to the colonies. Our brethren who visit foreign countries in the public service have leisure and opportunity for cultivating comparative anatomy and natural history, which practitioners at home do not enjoy; and we are not acquainted with any work which the authorities referred to (who have always been foremost in encouraging such liberal pursuits) can recommend so properly to gentlemen who are likely to enjoy good opportunities of cultivating comparative anatomy.

MEDICAL GAZETTE.

Friday, March 15, 1844.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medice* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

DECEASE OF SIR HENRY HALFORD.

It is this week our painful task to record the death of Sir Henry Halford, which took place on the evening of Saturday, the 9th instant, at his house in Curzon Street, in the 78th year of his age.

Sir Henry had long suffered from occasional attacks of pain, occupying the situation of the nerves of the upper and lower extremities of the left side. These had latterly increased in intensity, assuming all the appearance of tic douloureux, and only yielding to full doses of opium. After a time the sto-

mach gave way, when the emaciation and debility became progressive, till at length he expired in a state of extreme exhaustion, notwithstanding every effort on the part of his medical attendants (Dr. Seymour and Dr. Hawkins) to support him.

The deceased was born at Leicester, on the 2d of October, 1766. His early education took place at Rugby School, after which he went to Christ's College, Oxford; and thence, on the completion of his terms, he proceeded to Edinburgh, then in the height of its celebrity as a medical school.

Having thus finished an education of the highest order which the establishments of the country afforded, he settled in Leicester, practising jointly with his father, Dr. Vaughan, the most eminent physician in that part of the kingdom.

In 1792 he came to London, and very rapidly obtained extensive practice. In 1795 he married the Hon. Elizabeth Barbara St. John, second daughter of Lord St. John. He was created a Baronet by George the Third, and changed his name from Vaughan to Halford, in compliance with the will of his cousin, Sir Charles Halford, whose estates he inherited.

In February, 1793, he was elected physician to Middlesex Hospital, an office which, however, he held but a short time, having resigned it in December, 1800.

In 1820 he was elected President of the College of Physicians, an office which he continued to hold up to the period of his death, having been annually re-elected.

Sir Henry, as we have said, acquired an extensive practice very soon after he came to London, and for many years afterwards ran a course in this respect similar to Baillie's; while after the death of the latter, in 1823, he was for some time almost without a rival. He was

physician to four successive sovereigns, George III., George IV., William IV., and her present Majesty; while he also attended numerous members of the royal family,—and is said to have been consulted by several of the potentates of Europe.

Sir H. Halford possessed considerable classical and literary attainments, and was justly regarded as an accomplished gentleman. As a physician his excellence was generally regarded as residing chiefly in the power of prescribing for symptoms so as to palliate suffering, in which respect he far surpassed his rival, Dr. Baillie, whose excellence, on the other hand, lay in his greater knowledge of pathology.

Sir Henry was considerably under the middle stature, of intelligent countenance, and refined manners; indeed, in the opinion of many, the polish was such as to reflect the sentiments of those who approached him rather than to display his own.

Sir Henry certainly had a large share of professional zeal, and to him mainly, if not solely, is to be attributed the establishment of the evening meetings at the College of Physicians, which, for some time, proved so successful and attractive. Here were originally read most of those essays which he subsequently published, and the popular character of which rendered them extremely well suited to the mixed audience to whom they were addressed.

The following is a list of the Essays and Orations of which he was the author:—

On the Climaeterie Disease.

On the necessity of Caution in the Estimation of Symptoms in the last stages of some Diseases.

On the *Tie Douloureux*.

Popular and Classical Illustrations of Insanity.

On the Influence of some of the Diseases of the Body on the Mind.

On the *Kauros* of Aretæus.

Oratio in Theatro Collegii Regalis Medicorum Londinensis, ex Harveii instituto, habita die Octob. xviii., an. M. DCCC.

Oratio in Collegii Regalis Medicorum Londinensis Edibus novis habita die Dedicationis, Junii xxv., M. DCCC. xxv.

An Account of what appeared on opening the Coffin of King Charles I., in the Vault of King Henry VIII., in St. George's Chapel, Windsor, on the 1st of April, 1813.

LONDON MEDICAL SOCIETY.

THE 18th anniversary of this Institution took place last Saturday, Mr. Pileher (President), in the chair, when an oration on the benefits conferred on science by the microscope was read by Mr. T. Bell.

The Fothergillian gold medal was then presented to Mr. Roberts; the first silver medal to Mr. Clifton, of Islington; and the second to Mr. T. B. Maurice, of Reading, for his performance of the Cæsarean operation.

The members and various friends afterwards dined together at the London Coffee House.

EXAMINATIONS FOR HONORS.

To the Editor of the Medical Gazette.

SIR,

You would do me a great kindness by inserting the following observations on the subject of Prizes in an early number of your journal.

I am, sir,

Your obedient servant,

W. F.

London, March 5, 1844.

I venture to bring the subject of examination for honors before those teachers whose agreeable duty it is to reward in some measure the deserts of the industrious medical student, in order that if the remarks which are offered meet their views on the subject, the close of the present session may show that they receive in a friendly manner any hints which may be given as to the modification of the examinations as at present conducted. There is a great difference in the mode of determining which student is most deserving of the chief honour to be awarded; in some schools, he who has written the longest essay on a given subject, looking rather to quantity than quality, is selected; this is, however, not so commonly the case as it was a few years ago. Again, a candidate who has given the preference in

his essay to the opinions of his teacher, has thus, by a little of that potent ingredient, flattery, obtained a prize.

It will, however, perhaps be better to give the different modes of examination, and from these will be seen which is the most fair way, and by which the most *really* deserving student can obtain the highest honor. The examinations must necessarily vary according to the different branches of science; those mostly adopted now are—1st, *circa voce*; 2d, by writing an essay, with access to works written on the subject; 3d, by writing on a given subject, or subjects, no reference being allowed to books (the candidates being shut up); either in a given, or an indefinite time. These are the chief methods, being combined with a practical examination, or not, according to the subject.

The first is certainly a good way of testing a man's knowledge, and where the questions are varied and many, as in anatomy, midwifery, &c., it is, perhaps, the best; not, however, without a *practical* examination. The second plan is used by the candidates for the prizes awarded by the learned societies, &c., and is the only one which can there be adopted; in my opinion it is not by any means one for the examination of a medical student. The third is the one most frequently used, and is doubtless the best when combined with *practical* examination in medicine, surgery, &c. The mode pursued by the examiners at the University of London is generally agreed to be excellent, provided there be not too many subjects given, as was the case in the examination for honours last November, where the candidates had not nearly enough time given to answer the various questions as they wished to do. It seems better to limit the time, for a student can then write what is necessary, omitting much superfluous language, which another may feel inclined to insert; the objection to this chiefly is, the number of subjects for explanation too generally given: this, however, might be easily remedied. When no certain time is allowed, this mode of examination is sometimes abused by making it the means of accumulating "writings," heaps of paper filled with wandering descriptions of disease, rather than, as it ought to be, a concise and practical treatise on the subject required. How much better would it be if the professor of medicine would give for a subject *one*, instead of *all* the diseases of the chest and head; or the teacher of surgery *one*, instead of *all* the following, diseases of the testis, urinary organs, diseases and injuries of bones, &c. which is too often done. I know that candidates for a prize have been obliged to remain shut up in one close room for *sixteen hours* before they could finish the task allotted them, and this for two days in succession. This seems as if the

Professor wished to get as much as he could in exchange for his prize, or even as if he thought he may altogether evade giving his prize, hoping that the candidates would be unable to accomplish the necessary task. Practical examination, however, is, I hold, the most necessary, as well as the most fair, in every thing. In anatomy it is generally used; not so, however, in medicine or surgery; and in one of the schools the successful candidate for the midwifery prize (that most practical of all practical subjects) had never attended a case of parturition.

Surely, in the examination in surgery, a subject might be obtained for the candidates to have an opportunity of showing their manual dexterity and skill. The wards of the hospital will always furnish patients whose cases the candidate for honours in medicine may be required to diagnose and explain. Indeed, I cannot fancy that any teacher who really thought the awarding a prize was at all a matter for consideration, would determine without an examination by this means.

I now come to that part of the subject which is, in my opinion, very important as to the amount of honour which a prize confers on the receiver; and I wish to call particular attention to this point, namely, the impropriety of allowing all of the pupils to contend for the prize; and I deem it the more necessary to allude particularly to this, as in the list of awards we constantly find the names of those students who have devoted their whole time to one branch of study. The plan which is now adopted in many of the schools—I think I may say in all—of making a division of the anatomical class into a senior and junior, is a very good one, and it is to be regretted that it is not followed in all the classes, for many abuses would then probably cease. I put it to the sense of any one, whether it is fair and honest that all pupils should be allowed to contest a prize? Is it right that one should have an unfair advantage over another, as I will show some have? Now there are many of the students who have the very great advantage of residence in London, and to whom, therefore, the chief part of the expense incurred by those who live in the country is wanting. These are, therefore, able to give much more time to their hospital attendance, and instead of three years they have the privilege of attending five or six years, or even longer than this. It is obvious that there is great advantage to be obtained by this, and one effect is to give an unfair superiority, in regard to prizes, over the student whose stay in London is limited. The resident London student, as he is called, often attends to one branch of study every year, and thus, by giving his attention to the subject, must be better pre-

pared for an examination, and consequently will generally obtain the prize. On the other hand, the student whose time is limited must attend each year to a variety of subjects; for instance, during his first winter, lectures on anatomy, chemistry, materia medica, and surgery, are to be attended; and although his general knowledge may be much more than that of his opponent, he may be defeated in each trial to obtain a prize. I could instance many who have thus lost prizes. I have, I think, shown that this is very unfair; but there is yet another circumstance, with respect to senior pupils, which may be mentioned. It is often in the power of one man to pass his examination at the College at the end of his second winter, and he therefore has an opportunity of devoting all his third session to those subjects the prizes on which he is allowed to compete for, such as medicine, midwifery, &c. Again, if a man passes the Hall, he is not disqualified to try for the surgical prize, having an opportunity of giving up his whole time to this branch of study. This also seems to me to be most unfair. There is only one mode of examination which would effectually prevent partiality, and this consists in having an examination at the end of each session, for first, second, and third year pupils. These examinations should be general, and of what they consist may be easily determined by the teachers. This is, I think, the only fair and honest method of testing a man's proficiency; and I would add, it is not one branch of study alone that makes a good practitioner of medicine or surgery, but it is the practical knowledge and experience (for a pupil of twenty-one may have great experience) which he has obtained, by the only method of information which is truly valuable, when compared with others, namely, the study of disease in the wards of the hospital, and at the bed-side of his patient.

One word with regard to the prizes. Medals are now much in fashion, but how many students would far prefer books or instruments, as being much more useful. There are generally one, two, or three prizes, and certificates, but how much more valuable are these at one school than at another! I see in the list of prizes published in the GAZETTE, May 1843, a teacher of surgery at one of our schools gave one prize only, *and no certificate*; at another, where certificates abound, as many as *twenty* have been distributed. Now, it may be thought that one certificate is as good as another, by those who are not aware of this vast difference in number; but how much more valuable that single one, where only one is given, is, than one out of twenty, I leave them to determine. It is very hard, because one certificate (which is the usual number

with one professor) has been given, two or three candidates who have passed an excellent examination, a very little inferior to the best, should not be noticed; it would, in my opinion, be proper to exceed the usual number, rather than not grant the reward to merit.

I have thus very imperfectly given my opinions on the subjects of prizes, and I do not think I shall say too much if I add, that many students anxiously look for some alteration in the system of prize distributions. I have hopes that the different teachers will pardon me, if they think I have at all infringed on their peculiar province, and if any of the observations I have made meet their views on the subject I shall be much gratified. I trust that in future there will be no ground for mistrusting the impartiality of the teacher, or the qualifications of the successful candidate; and that prizes will become, as they were originally intended to be, the mark of approbation of the teacher, and of merit and qualification of the pupil, and not the sign of good fortune obtained by the one, or the constrained gift necessarily bestowed by the other. Truly useful shall I esteem this communication, if it lays the foundation, in ever so slight a degree, for a correction of these imperfections, I will not say abuses, which exist in most, if not all, of the schools of medicine in this metropolis.

A LETTER FROM HAMBURGH.

VIRO DOCTISSIMO,

EDVARDO HUTT BROWNE,
Medicinarum in Mancunio practicum, S.D.
ADOLPHUS ROSENBLATT, Ph. D.

SEX menses abierunt à quo tempore amœnas inter latebras Blankenesæ Albem nostrum quasi speculo τὴν σκηνὴν reddentem mecum admiratus es. Disserentibus de omnibus rebus et quibusdam aliis tandem accidit de te coquinariâ aliquid disputare; et inter nos conventum est, fœcula cujusque terræ præstantiora, si Latio donata forent, per ora virum facilius volatura esse. Hujusce colloquii primitias tibi mitto præscriptum de placenta Anglorum celeberrimâ Latine redditum.

AN EXPERIMENTAL FAST.

THE *Gazette Medicale* of Feb. 24, 1844, contains a curious paper by a country physician, entitled *un carême* (a Lent.) He observes, that in Paris Lent passes away unperceived; while in the country the practitioner is often consulted by persons who want to know whether and in what degree they may fast, without injury to their health.

The writer, who appears to have fasted from religious motives, but also as a physiological experiment, kept the Lent of 1839 in the following manner. He rose on the average at 6 o'clock, and ate nothing till 12. At noon he dined, his meal consisting of eggs, fish, vegetables, and dessert, except during the last three days of Passion-week, when eggs are not eaten. At 8 or 9 in the evening he supped on cheese, sweetmeats, and stewed or dried fruit. He did not take milk at this repast, as it is only allowed in some dioceses. Nor did he eat plovers, coots, sea-ducks, or any other aquatic birds, though permitted by the church. As to quantity, he always satisfied his appetite, the fatigues of his profession not allowing him to do otherwise. On Sundays he did not fast, as it is not required. Moreover, he once broke the fast, ten days before Easter. He had passed the night at a labour, from which he had to return on foot, and had the prospect of a hard morning's work before him. A saint, he says, could not have done otherwise. Every ten days he was weighed, and tried his strength by means of a steelyard; he also made daily notes of what concerned his appetite, his digestion, the alvine and urinary evacuations, the genital functions, sleep, and his general state of comfort or discomfort, both physical and moral.

He did the same thing for a month before the commencement of Lent, and a month after its termination. His weight varied but little, being never less than 60 kilogrammes, or more than 60½. On Easter Sunday he weighed 60½, being exactly as much as on Shrove Tuesday.

A kilogramme = 2 lb. 3 oz. 4 dr. 2·45 gr. Avoirdupois; so that 60 kilogrammes = 132 lb. 6 oz.

The variations in his strength, as measured by the machine, were greater, but did not lead to any satisfactory conclusion.

His appetite was not much influenced by Lent. It failed him now and then, but not so frequently as in the previous or in the subsequent month.

His digestion, in like manner, was about the same, the unfrequent and slight inconveniences which he noted occurring indifferently during Lent or the subsequent month; but more frequently during the previous month, on account of his dining out; for frequent dinings-out he found more difficult to bear than keeping Lent. "You will fancy," he says, "that I was constantly dining out, and be scandalized at it. As a compensation, think of my Lent. Besides, the reputation of us doctors is already fixed, and I have nothing to lose."

It is said that lenten diet is heating, *i. e.* constipating, and much more so when combined with total abstinence. This the author found to be true. From Jan. 13th to Feb. 13th, being the month which preceded Lent, only three days passed without a stool; and only two in the month which followed Easter Sunday; while there were nine during the forty-six days of Lent. This was not alarming, and he did not suffer from it; but he is aware that in many persons the constipation thus produced is much more obstinate, and consequently much more inconvenient. In his case, the influence of diet was modified by exercise in the open air, the necessary attendant upon his profession.

The contrary state, or diarrhoea, occurred twice, each time for a day, in the month which preceded Lent; once during the month after Easter; and never during Lent. On one day he had two stools, which is unusual with him; and occasionally slight colic from the use of prunes.

His sleep is generally good, but was less so during Lent. It was disturbed or broken nine times during the month preceding Lent, nine times during the month after Easter, and nineteen times in Lent; and as he had less to disturb him in Lent than the preceding month, he very reasonably supposes that the diet had some influence.

"Sleep is subject, as every one knows, to strange aberrations, particularly if a man lives continently; and I did so. It was by this that I sought to measure the aphrodi-

ON MUSK.

siac power attributed to fish. For occurrences of this kind my notes give me the number 5 during the thirty days which preceded Lent, 5 during the thirty which followed it, and 6 during the forty-six days of Lent itself. Hence I found myself in Lent rather below what I consider my normal state in this respect, though I ate a great deal both of sea and river fish. So that to judge by my personal experience, the prolific power attributed to ichthyophagous nations by Herodotus and other historians, and also by physicians, would seem very problematical."

The conclusion which he drew from the sum of his sensations was, that lenten diet, even of the best kind, is a poor thing for a man accustomed to eat meat. Fasting, *i. e.* total abstinence, is still more weakening. The latter part of his mornings (particularly after 10 o'clock, his regular breakfast hour) passed away in great discomfort, in a sort of torpor, dullness, and sleepiness, which he found it difficult to struggle with, in spite of the presence of patients. At that time, too, and, in a less degree, during the whole day, he felt himself more sensitive to cold than usual. Putting aside total abstinence, which he seems to have observed only that year, and passing over some very few infractions, he kept Lent, he says, for seven years running.

As he supposes that his *cher confrère* at Paris has not many patients who consult him about keeping Lent, he sends him this narrative as an experiment on a particular kind of diet. He thinks that the ancients knew more on this point than we do, and that the majority of practitioners are reduced to the mere notions of cooks, about eel being heavy, and haricot beans flatulent. Others have got beyond this, and will tell you confidently of some very few aliments which have been analysed, that they are nourishing, or not nourishing, seeing that they contain such or such a proportion of azote. Yet, in spite of these analyses, the peasant and labourer, though fed upon something declared not to be substantial, can easily carry weights, which the citizen gorged with azote could not lift. "Doctors, give up your whim; or let the workers in science divide their toil; and while some penetrate into the very bowels of nature, let others take up a mode of observation more extensive, though less deep, and just inform us of the action of substances on the organs of man."

[Our readers will find Dr. Stark's dietetic experiments on his own person worth perusing.—TRANSLATOR'S NOTE.]

FROM St. Petersburg and Moscow there is annually exported a quantity of Russian musk, amounting on an average to 500 pounds. Perhaps one half of this quantity is destined for the London market, where, more especially, the smallest bags are in demand, whilst the remainder is distributed amongst other European markets, more especially those of Holland and Germany, where the greater part is consumed.

The Russian musk, when exported from Russia, is always genuine and unadulterated; the bags never being opened, are consequently never sewn, or closed in any artificial manner. Sometimes it is obtained so fresh, that moisture may be expressed therefrom by cutting through the fleshy side of the bag. The interior mass is frequently of a soft and pappy consistence; externally, however, the bags are perfectly dry.

Dyrssen, an eminent Russian merchant, proved to Dr. Goebel, by his books, that he annually exported, on an average, about 200 pounds of Russian musk, and he stated, that through other houses at least a similar aggregate quantity was sold; and, lastly, from Moscow, in the winter, there was sent, *via* Brody, to Vienna, and through other channels, at least 100 pounds, giving an annual total of 500 pounds of Russian musk, which was rather below than above the average quantity exported.

If we take a Chinese musk bag, with its partially bald surface and yellowish-brown hairs here and there cut off, and soften the same by digestion in warm water, we perceive pretty plainly that it has been subjected to artificial changes. The external skin is tender, and may easily be torn, as if it had been destroyed by partial decomposition; the hairs have either fallen off or been removed by force: indeed, the longer hairs clearly appear to have been cut off.

Why do not the musk bags from China arrive as perfect as those from Russia? Because the contents have been removed and the bags refilled, as may be distinctly perceived by those hairs which surround the interior small opening which is found on the hairy side of the bag, immediately before the genital canal, being depressed; whilst in the Russian musk bags these small hairs are found standing obliquely, and protruding in and between the secretion. It is possible, although not at all probable, that the musk deer, which abound in Thibet, Butan, &c. may possess musk bags of a perfectly distinct character from the Russian, but no trustworthy reference or practical judge has ever witnessed the removal of such a bag from the living animal, or described it and its contents. That the grain musk of the Chinese musk bags which have been brought

to Europe, differs very much in its effects, as well as in its physical and chemical characters, from the pure Siberian, has been ascertained; and that it likewise acts with more energy on the living economy when administered internally. All the different chemical investigations of musk, for which we are indebted to Buchner, Wetzlar, Oberdoeffler, Thiemann, Blondeau and Guibourt, Gieger and Rieman, &c., taken together, afford very few hints in reply to those questions, which involuntarily present themselves, in reference to the two different kinds of musk, so far as regards their chemical and mercantile relations.

Taking, therefore, the most essential points of the preceding communication—

I. That the Russian musk is always sold in perfect bags, and exported in considerable quantities to China and to London.

II. That from China to Russia no direct exportation of musk takes place.

III. That the Chinese musk can only be obtained *via* London.

IV. That the Chinese musk bags never arrive unopened.

V. That it appears most undoubtedly that the mass has been taken out and replaced.

VI. That the external appearance of the bags proves sufficiently that they have undergone artificial treatment.

VII. That frequently the secretion apart from the bag is imported from China, leading to the inference that a sufficient number of bags cannot be obtained wherein to put the quantity increased by adulteration.

Taking all these reasons into consideration, we think the conclusion announced at the commencement cannot be avoided, viz., 'hat the distinctly marked difference of the Chinese from the Russian musk, if not wholly, is at any rate chiefly, caused by the treatment which it undergoes in China; and therefore that Chinese musk is the natural product after it has been modified by artificial means.—*The Chemist*.

THE BEST MODE OF EXAMINING THE FORM, STRUCTURE, AND MOVEMENTS OF VIBRATILE CILIA.

TAKE a very small portion of the gill of the sea-mussel, and with a pair of needles detach a small piece of a single bar of it, or a small portion of two or three bars, and separate them a little distance from each other. Place the portion of the branchia so prepared in an animalcula case, or upon a slip of glass, and immerse it in some of the fluid from the shell of the animal; then cover it lightly with a piece of thin glass or with mica. The portion of gill so prepared will exhibit several rows of cilia, which, if the animals from

which they have been taken be alive at the time of the removal of this portion of the gill, will be seen in active motion of a fanning or a lashing kind. We may here state, for the information of those of our readers who may not have witnessed this phenomenon, that no cause for it, no motor power, has ever been perceived. It is perfectly independent of the vascular and muscular systems. Contact with the blood is not necessary to its continuance, since it continues just as active when removed from that fluid. It is independent of muscular motion, since it endures longer than the contractility of muscle after death; also, by preventing the blood from flowing to a limb, the muscles become paralyzed; the ciliary movement, on the contrary, as before stated, is unaffected by this withdrawal of the blood. Shocks of electricity passed through the ciliated parts, and the application to them of prussic acid, opium, strychnia, and belladonna, which all powerfully affect the nervous system, produce none upon the ciliary movement—the only thing necessary for the continuance of this movement being the integrity of the epithelial cells, to which the cilia are invariably attached in man and the higher animals. The best time for observing the character of the motion, and the form and structure of the cilia, is some hours after the bar has been prepared, as above directed, and when the movement has become sluggish.—*London Physiological Journal*.

TARTAR EMETIC IN TARDY LABOUR.

DR. GILBERT, of Gettysburg, says we are frequently called to cases in which labour has commenced, but the progress is slow, both on account of the insufficiency of the uterine contractions and rigidity of the os tincæ. These cases are most frequently found to occur in patients of tense fibre, and rather robust constitutions. Bleeding produces some relaxation, but rarely hastens the labour; since, in most instances, it does not add anything to the vigour of the pains. Several years ago, while in attendance upon such a case, wishing to expedite the labour, I felt a very strong desire to administer the *secale cornutum*, but was prevented by reflecting upon the well-ascertained effects of that powerful agent under such circumstances. The question whether some other article of the *materia medica* might not be advantageously exhibited, then presented itself to me. Relaxation of the *os uteri*, and expulsive contractions, were the principal desiderata. Emesis in the commencement is always looked upon as a symptom of labour; *ergo*! also produces nausea, and

frequently vomiting. In evacuating the stomach, the diaphragm, abdominal muscles, &c. are called in violent action: these same muscles aid the uterus in its expulsive efforts; hence emesis may be looked upon as a powerful means of exciting labour and producing efficient expulsive contractions of the uterus, because the same set of associated organs are in action; and such is the sympathy between the stomach and uterus, that contractile efforts are easily transferred from the former to the latter, the more especially since the uterus is about to take on such action of its own accord. Again, while emesis excites, and is accomplished in part by the associated contractions of the muscles constituting the abdominal parietes, it also produces relaxation of the other parts of the system, and of none more certainly than the os uteri, under these particular circumstances. Reasoning thus, I was induced to make a trial of tartrate of antimony and potass, in doses of half a grain the first portion, and then a quarter of a grain every fifteen minutes, until emesis; as soon as retching commenced, the uterine contractions strengthened, and the labour terminated speedily. I have frequently used the tartar emetic since, and always with the most satisfactory results.

I was not then aware that this remedy had been used by Ramsbotham, who, speaking of rigidity of the os uteri, says that "antimony, in doses sufficient to keep up a feeling of nausea, has been exhibited in these cases with marked effect."—*New York Journal of Medicine*.

CURE OF SCIRRUS BY IODINE.

By DR. FRIEK, OF GOLDAPP.

DR. FRIEK, being consulted in a case of scirrhus of the breast, successfully combated this disease by the employment of iodide of potassium externally in the form of ointment, and internally according to the following formula:—

℞	grammes.
Hydrolate of melissa.	60
Iodide of potassium.	4
Compound elixir of oranges. . .	15
Mix and dissolve.	

For a mixture, of which a tea-spoonful is administered morning and evening, at the commencement, in a cup of gum and water, suitably sweetened.

The dose should be gradually increased, according to the effects.

The author affirms, that, under the influence of this treatment, maintained for 26 weeks, the scirrhus was radically cured.—*Chemist*.

ROYAL GENERAL DISPENSARY.

ON Wednesday, the 13th inst., Dr. James B. Thompson was elected to the office of physician to this institution.

APOTHECARIES' HALL.

ON IRRITATION.

AND

IRRITATIVE OR SURGICAL FEVER.

By R. A. STAFFORD, F.R.C.S.

Surgeon Extraordinary to H.R.H. the Duke of
Cambridge; Senior Surgeon to the St. Mary-
lebone Infirmary, &c. &c.

THE art of healing external wounds and injuries is termed surgery; whilst the treatment of internal diseases is denominated physic. But, although there is an artificial distinction made between them, for the sake of dividing the offices of the physician and surgeon from one another, yet from the symptoms which occur in both they may be considered almost indivisible. For instance, when an injury is received, such as a wound of any of the soft parts, a fracture of a limb, or the introduction of a morbid poison into the system, we see pain and fever arise, a quick pulse, furred and dry tongue, restlessness, want of sleep, delirium, syncope, death. The same is seen in internal disease. An individual shall get inflammation of the lungs, of the bowels, or any internal part, quick pulse, fever, restlessness, want of sleep, delirium, faintness, and death will supervene. It may be observed, therefore, the same symptoms occur in both: consequently the division is merely artificial. It is the duty, however, of the surgeon to treat local disease; and therefore I shall confine myself to that subject.

Before I describe any specific disease, I must first offer some explanation of the meaning of the word Irritation.

Irritation may be produced in two ways; general, as we see in typhus fever, &c.; and local, such as that produced from the formation of an abscess, an operation, or fracture of a limb. When irritation is general, as in typhus fever, &c. we can discover no apparent cause for it; there is nothing to be seen,

and all we know is, the symptoms attendant upon it, and that the individual has fever. But when irritation of the system is caused by a wound, abscess, fracture, or operation, we see the reason of it; one of these causes have produced it; the symptoms are the same, and the same effect therefore is produced.

There are two descriptions of local irritation; the one, that which affects the whole frame; the other where only a part is affected by it. That which affects the whole frame is caused from accidents, the sudden formation of matter, or from chronic disease. An individual meets with an accident; concussion of the brain, a general shock of the body, a compound fracture, or a compound dislocation. What is the consequence? Why, first there is a general state of collapse and depression, but as the nervous energy recovers, and the circulation increases—that is to say, reaction takes place—fever comes on, the pulse is quickened, there is thirst, hot and dry skin, delirium, and other concomitant symptoms. Mr. Abernethy called this “surgical fever,” and I do not think any one can offer a better definition. It is “surgical fever,” that is, a fever brought on from an accident, formation of pus, or a disease of a joint, &c. A good illustration of this is seen in urinary abscess. A patient having a stricture gets urinary abscess. It is not at first discovered. He has fever, which runs on into a typhoid character. He is treated for typhus fever. He has all the symptoms; heat of skin, quick pulse, dry and black tongue, like a tile, an oppressed and anxious countenance, extreme emaciation, delirium, and an exhaustion threatening death. It is discovered there is an urinary abscess; it is opened; putrid urine, pus, and sloughs are let out: the symptoms gradually vanish, and the patient recovers. I have seen such cases as these, and therefore it behoves the physician as well as the surgeon to find out, when there is fever, whether

there is local disease producing it. I remember a case in St. Bartholomew's, where a gentleman was house-surgeon there, that was admitted into the hospital as typhus fever, the patient being sent in for such disease. He was treated accordingly, and nothing was suspected of there being anything wrong about the urinary organs. The sister of the ward, however, observed that the man did not make water, and came to me, as it was her duty to do, to inform me of it. On seeing him I found him in the following state. He had an excessively quick pulse, black and dry tongue, an oppressed countenance, and was delirious. On examining the pelvic region, and that of the urinary organs, I found in the perineum an immense urinary abscess, which was producing all these symptoms. It was opened, and a vast collection of putrid sloughs, and pus and urine, let out. The typhoid symptoms gradually abated, and the man ultimately recovered.

I could relate several instances of local irritation producing the same symptoms as typhus fever. A medical gentleman, of great practice in the suburbs of London, was seized with irritative fever, which ran on until it assumed a typhoid character. Every body considered he had typhus fever; but he had a great friendship for Sir Astley Cooper, and it was wished by his friends he might see him. Sir Astley, with his usual kindness, visited him. Immediately on entering the room and looking at him, he said to his attendant, "Pray, sir, where is the abscess?" The answer was, "There is no abscess, Sir Astley."—"I am sure, sir, there is; let me examine him all over the body." He did so, and found a vast collection of matter in his side, which, strange to say, had given the patient no pain. It was let out, the fever subsided, and he got well. I remember a case of the kind myself. A surgeon, a friend of mine, belonging to a public institution, while opening a body pricked his finger. On the same evening inflammation and swelling took place in the wound. The absorbents inflamed, and he had irritative fever. Pus formed in various points of the arm, and matter was let out; an abscess formed in the axilla, which was opened. Still the irritative fever continued, and from the oppression, the exhaustion, and the death-like feeling, more was suspected. He had some pain in his right side; a fulness and tension in some parts was observed, with a deep redness of the skin, but no fluctuation could be discovered. The symptoms were so distressing, threatening dissolution, that it was agreed upon in a large consultation of surgeons to make an incision in the part. This was done, and although no pus escaped at the time, great relief was obtained. In a day or two

matter escaped from the wound in profuse quantities, and the patient taking tonics, such as quinine, &c. and generous diet, soon got well.

And now I shall speak more particularly of sympathetic or irritative fever, arising from accidents; or rather, as Mr. Abernethy called it, "surgical fever." When an individual meets with an accident he has to encounter two effects; the first shock, and the after consequences. The first shock always causes a collapse, and sometimes it is so great that reaction never takes place; death ensues. In collapse the pulse is hardly perceptible, there is a marble coldness over the whole frame, and exhaustion resembling death. The case of Mr. Huskisson was one of this kind, who, being a nervous man, got his thigh crushed by a train on the first opening of the Liverpool and Manchester railroad. The shock was so great, that reaction never took place: nature took the alarm; she was aware she could not repair the injury; the nervous system was quite overwhelmed and exhausted; he sunk and died. Such cases are not very uncommon, but I have mentioned this because we all know the fact, and it was felt and deplored by all. I shall not relate any more cases, because, as you attend to the hospital practice, you will see them every day.

The second consequence of an accident is irritative, sympathetic, or surgical fever. The stage of collapse has passed, the pulse begins to rise; there is restlessness, heat of skin, thirst, fever, &c. These symptoms all increase, delirium comes on, and typhoid symptoms. But I will relate a case; and I cannot do better than, by following Mr. Abernethy's example, give an instance of compound fracture. An individual in full health has the misfortune to be thrown from his horse, to fall from a scaffold, to be driven over, or to meet in some other way with a compound fracture of a limb; the arm, the thigh, or the leg. He at first has the stage of collapse as I have described; he is almost pulseless, cold, and exhausted. He gradually recovers from this state, the pulse becomes stronger, and he runs on into a state of fever. The whole nervous and sanguiferous system is deranged. The pulse increases in strength and fulness; there is heat of skin, fever, furred tongue, high coloured and scanty urine. He may dose, but sleep has left him; he starts and is agitated when roused. His appetite is gone, he is restless; his bowels are inactive, and the very foundation of nature is shaken. He may feel strong in his own imagination, but it is over nervous excitement: his strength is a proof of his weakness.

This state of things goes on for a few days, three or four or so, when either a

favourable change takes place, or a fatal termination of the case is threatened. When favourable symptoms occur, the wound suppurates kindly; the pus is of a healthy character, and the pain begins to subside. The fever gradually diminishes, the frequency and strength of the pulse becomes less; the secretions alter their character, and are more healthy. The distress and anxiety of countenance diminish, and the nervous excitement and circulation is more tranquil: indeed, all the alarming symptoms disappear. When, however, the case puts on a more alarming aspect, the fever continues, and runs on into a typhoid character, the wound alters, it becomes dry, and of a brown or tawny hue; there is little or no secretion from it. The extremities of the bones, if they can be seen, also become dry; the whole presenting a most unhealthy character, disposed to mortification, with a most disagreeable odour. The pulse at this time is very rapid and irritable. The countenance flushed with hectic, and round the wound there is frequently an erysipelatous blush. There may, or may not, be delirium; but most frequently the patient more or less wanders. The symptoms in the last stage assume a typhoid character; the tongue is dry and black, rough to the touch; the pulse quick, small, and irritable; the patient has constant delirium, and rambles, generally on subjects connected with his earthly occupation. Perhaps he talks to his horses, if a carter or a coachman; if a schoolmaster, of his scholars; if a farmer of his stock, and so on, as the occupation may be; but all wildly and incoherently.

The subject of the delirium is uncertain, and more often is of a melancholy kind; but sometimes it is gay and lively, and the patient appears quite happy. At the last close of the case he picks the bed clothes, and appears as if he is catching flies, or that he sees something which he wishes to pick up. Death is now near at hand: after these symptoms there is but little hope of recovery. Shakspeare has beautifully illustrated the last stage of disease, when he makes Dame Quickly say, at the death of Falstaff, in the play of Henry V.—“A’ made a finer end, and went away as it had been any christom child; ‘a parted even just between twelve and one; e’en at turning of the tide; for after I saw him fumble with the sheets, and play with flowers, and smile upon his fingers’ ends, I knew there was but one way; for his nose was as sharp as a pen, and ‘a babbled of green fields. How now, Sir John, quoth I? What, man! be of good cheer. So ‘a cried out God, God, God! three or four times. Now I, to comfort him, bid him ‘a should not think of God. I hope there was no need to trouble himself with any such thoughts yet. So ‘a bade me lay more clothes on his feet.

I put my hand into the bed, and felt them, and they were as cold as any stone, and then I felt his knees, and so upward and upward, and all was as cold as any stone!”

In death caused from local irritation, the brain no doubt suffers some alteration of structure. There is serous apoplexy, that is to say, serum in the ventricles producing pressure; softening generally, or in different spots, or want of supply of blood to that organ.

When vital parts are wounded the constitutional disturbance is immense. There is an excessive anxiety and distress of countenance; the circulation is hurried, the pulse being most rapid. If blood be taken—and the treatment generally demands it—it will be cupped and buffed. The pulse is not always stronger than in health; it frequently is smaller, but hard, and rises when blood is taken. A gun-shot wound of a vital part is a good illustration of the state of the circulating and nervous system. In gun-shot wounds the bullet may traverse through more than one vital organ; it may pass through the lungs, the liver, or the intestines. When such is the case, the constitutional derangement is very great; there is distress and anxiety of countenance, and excessive pain at the part wounded; quick irritable pulse; fever; exhaustion; convulsions, and usually death. In strangulated hernia the same is seen. Here a portion of intestine is incarcerated, a vital part; inflammation of the peritoneum takes place; extreme tenderness and pain of the abdomen; distress of countenance; constant sickness; quick, hard pulse; fever; and, unless relieved by operation, mortification and death follow.

When local injury has continued for some time, and irritative fever attends it, it then may be termed chronic: that is to say, the first stage is passed, the violence of the fever has subsided; but still an irritative and continued fever is kept up from the local injury. This is instanced by a compound fracture. When reaction has taken place after the first shock, the fever and concomitant symptoms are very violent, but they gradually subside; they become more equalized; the fever remains, but is not so violent, and as the patient recovers, and union of the bone takes place, it abates and goes altogether. If, however, the case is likely to terminate unfavourably, the fever then runs on into hectic, and the worst symptoms occur. A lumbar abscess is a good example of irritative fever. Here we see irritative fever arising from the formation of pus; the skin is hot and dry; the pulse extremely rapid; thirst, furred tongue, and distress of countenance, &c. At length an abscess points in the groin, the thigh, or elsewhere. It is let out, the violence of the fever subsides; but it runs on into a chronic form, as long as a

secretion of pus takes place, and if the disease of the vertebræ be great, and does not amend, hectic fever supervenes.

Hectic fever may be considered the third stage of surgical fever. It occurs when disease has continued for a considerable time, and generally when the case becomes hopeless. I do not mean, however, to say that no case recovers after hectic has appeared; I have seen several cases, after this symptom has been present, get well. Hectic has its paroxysms, and generally comes on in the evening, the fever being less during the day. It is attended by a flushed countenance; quick pulse; heat of skin; thirst; and the face, from the beautiful red blush and bright eye, may be said to look brilliant: but it is the brilliancy usually preceding death. After this stage of fever is over, profuse nocturnal sweats come on, and in the day there is a diminishment of febrile action. We see hectic fever arise in long-continued disease, such as of the hip-joint, the knee, and the vertebræ, in chronic abscess, where there has been a profuse discharge of pus, disease of the bones, scrofulous diseases, accidents of long duration, and wounds where a vital part is injured, consumption, and other internal injuries.

But there are varieties of irritative fever. For instance, if an individual meets with an accident, it is not uncommon for it to stir up some old disease he has been subject to. Erysipelas perhaps, the gout, or ague. In wounds it is very common for erysipelas to ensue, and more particularly if that disease is constitutional. Hence, if a patient has been liable to it, and should meet with an accident, get a wound, or undergo an operation, he is disposed to an attack of this disease. I have known several instances where amputations have been performed upon persons who have been subject to this disease, and erysipelas has appeared on the stump. A case of this description occurred in my practice a few months back. I amputated the thigh of a woman who was subject to this disease. In a few days after the operation it made its appearance on the stump. The same in amputation of the breast. A female whose breast I removed for cancer was likewise liable to erysipelas. An attack of this disease made its appearance round the wound, and it was with difficulty the patient got through it.

In injuries of the head, when the scalp is wounded, erysipelas very often supervenes, and I have observed it more often occur in those who have been the subjects of it before. I have seen several cases of this description, and even lives lost in consequence. The late eminent surgeon, Mr. Vance, was *one* instance of it. He was thrown down stairs by a madman, and the scalp was wounded. Erysipelas came on, and he died. I remember several other such cases; so that I would

not even apply leeches on the head of a person who was subject to this complaint. I have known erysipelas come on from the application of leeches on the temples, to so great a degree as to endanger the life of the individual. It is of consequence, therefore, before you take blood in this way, to inquire whether the patient has ever had this disease before. Gout, I have said, might arise from an injury. I have seen such cases. I remember where a heavy piece of wood fell upon the foot of a man subject to gout. Leeches, evaporating lotions, fomentations, and other remedies, internal as well as external, were employed, but the inflammation did not abate. He at last mentioned he had been subject to gout, and suspected from his feelings that he had an attack of it. The hint was taken; he took colchicum, and other remedies for it, and the inflammation soon disappeared. During my practice I have seen three or four cases where gout has shown itself in the injured part, when the individual has been subject to the disease.

Ague very commonly occurs from local injury when the patient has previously had an attack of it. An injury of the urethra is a good example of this. It very often appears, if the canal is injured, that rigor soon after comes on, exactly like the shivering fit in ague; it is followed by the hot stage, and afterwards the sweating stage. It would be difficult to tell the difference, was not the cause known: I have seen the irritative fever attendant on accidents run on into intermittent fever. The following case I well remember. A gentleman of distinction was riding in frosty weather in Regent Street, and the ground was very slippery: his horse slipped up, and fell upon his side, with the gentleman's foot under him. As soon as the horse got up he was taken into a shop, and I was sent for. I soon saw something was very wrong about the foot, and therefore cut the boot off. I found that the tarsal bones were dislocated from one another; an accident of very rare occurrence—so rare that its possibility is doubted; but Baron Dupuytren, Lisfranc, and other French surgeons, under whom I studied for a certain period, describe this dislocation. A surgeon of very great eminence, and myself, reduced it, and the patient was taken home. Splints made of pasteboard soaked in hot water, and adapted to the foot, were applied. The pain, however, was most excruciating. Leeches, evaporating lotions, fomentations, &c. were frequently employed, but the pain continued for more than a fortnight, and at length took an intermittent form, coming on every evening about eight o'clock, lasting five or six hours, and then gradually abating, and the foot being easy during the day. The means of reducing inflammation were continued, but with no effect. The symptoms

were so peculiar, that we suspected it to be a case which put on an intermittent character. Quinine, therefore, was prescribed. The patient got better and better until he got well.

Tetanus often follows local injury; it is then called traumatic tetanus: that is to say, from a wound. It is not uncommon for this disease to follow an injury, and more particularly of the tendons. A slight cause will very often produce irritation sufficient to bring on tetanus. A man had a compound fracture of the ring finger of the right hand, and in eight or ten days he had trismus, and was admitted into St. Bartholomew's Hospital. The finger was removed, but the tetanic symptoms remained. No treatment succeeded, and he died. If tetanus has once taken place, the removal of a limb or part which gave origin to it does not afford the slightest relief. The disease being secondary is established, and cannot be overcome by any previous cause being removed. Some years ago a woman in the St. Marylebone Infirmary had a chilblain of the great toe which went on until it sloughed. Tetanus supervened. The removal of the toe was not of the slightest service: she died. I have seen many cases of tetanus, however, that have recovered. But I shall say more of this disease at some future period.

I have been speaking of local irritation producing general constitutional disturbance. I shall now speak of it where it is merely *local*. Irritation of a part is only when one organ is affected; the bladder, the rectum, the urethra, &c. without fever. An irritable bladder is a very common affection; an individual has constantly a desire to make water, but the pulse is not affected by it, or the general nervous system. There is no fever, hot or dry skin, or thirst attendant upon it. The circulation is carried on as quietly and tranquilly as if there had been no local irritation. We see the same in some ulcers, there is heat and pain; also in diseases of the skin, there being great irritation and itching, in glands where abscesses form, and many other parts, but there is no constitutional disturbance.

When there is irritation of one organ it is very common for another to sympathize with it; that is to say, there may be disease of one joint; the next to it will suffer pain, although there is nothing the matter with it; for instance, in a disease of the hip the knee sympathizes with it, and there is great pain in the latter joint; so, in disease of the knee-joint, the ankle is painful. In arthritic rheumatism this is peculiarly well exemplified; the disease goes from one joint to another in a most remarkable manner, and there is nothing for certain to account for it. Again, when there is stone in the bladder, there is pain at the end of the penis, disease of the

prostate gland, pain in one or both thighs. A blow on the head causing concussion of the brain will cause vomiting; a blow on the stomach, death; a sudden cessation of a discharge from the urethra, hernia humoralis; in fact, the instances of sympathetic irritation are too numerous to mention. They are to be accounted for through the nervous system. The nerves of the limbs are connected with the medulla spinalis, and through it with the brain, and thus any injury to the limbs will account for irritation of the whole system. Likewise any injury to an internal part will, through the sympathetic nerve, account for the same. But they both sympathize with one another, and therefore, wherever the injury may be, the whole nervous system will be deranged.

But local irritation is not always to be explained through the nervous system. In many instances local irritation takes place through the absorbents. For instance, an individual has ulcer on the foot, a hang-nail, as it is called, or an irritable sore on the leg. The absorbents inflame, and the inguinal glands become enlarged, and in some instances even pus forms. I have seen several cases of this description; indeed, it is not uncommon for a patient to present himself at an hospital with enlarged inguinal glands, not knowing the cause. On inquiry I have very frequently found an irritable ulcer on the foot, a hang-nail, or ulcer of the leg, and there has been a red line denoting inflammation of the absorbents. Many exemplifications could be adduced. The wound received in dissection is a good instance. A gentleman opens a body, or dissects. He pricks his finger; pain at the spot supervenes, the absorbents inflame, and the glands in the axilla become enlarged. Pus forms at various spots along the absorbents or in the glands, and is followed by the concomitant symptoms. Again, an individual gets a chancre. Through the absorbents the glands of the groin inflame and are enlarged, and bubo is the consequence. Numerous other instances of this kind could be brought forward, but it is unnecessary to recount them, as they will frequently be met with in practice.

The *treatment* of irritative fever depends upon the cause which gave rise to it. If from an accident, such as a compound fracture, concussion of the brain, a compound dislocation, &c. our object must be to reduce inflammatory action and fever. This can be done in three ways. By purging, bleeding, and opening the skin. In all cases of irritative fever, purging freely is of great importance. It tends to reduce febrile and inflammatory action more than any other means; indeed, unless the bowels are well opened, other remedies will not have their proper effect. A dose of calomel, followed up

by a compound senna draught every six hours, is the best method of clearing out the bowels, or castor oil. This being done, sudorifics may be administered, such as antimony, nitre, &c. and saline medicines given in doses according as the case demands. The fever may run very high, and bleeding may be required. This is a question of great moment, and ought not to be done rashly. We will suppose such is the case in a compound fracture, or compound dislocation. We find the pulse is immoderately quick, full, and strong. The skin hot and burning, and the tongue furred, and approaching to dryness. There can be but little doubt the patient ought to be bled; but before we do it, let us reflect. Let us remember, that although the symptoms demand depletion, yet that nature has much to repair. There is a compound fracture, a wound connected with a broken bone shivered in one or more places. To restore such injury great strength of constitution will be required. We ought, therefore, to bleed moderately, to reduce the over action of the sanguiferous system, but not to depress it. In injuries of the head more bleeding will be required; a vital organ has received a shock, and inflammation must be reduced. In chronic irritative fever, when the violent symptoms have abated, the skin should be kept moderately open, and the secretions attended to. Should the liver not perform its functions properly, small doses of mercury may be given, such as Pil. Hydrarg. Pulv. Hydr. c. Cretâ, and even small doses of calomel, such as that in the combination of Pil. Hydr. Sub. c. or Plummer's pill. These should be followed by a mild aperient the next morning, such as will act gently and without violence. If the strength is very much impaired, tonics, such as quinine, &c. may be taken, and nourishment, but it must depend upon the constitution of the patient, and the judgment of the medical attendant. The treatment of many individual cases of local irritation and irritative fever might be spoken of, but they are embraced in the particular classes of disease to which they belong; therefore it is unnecessary for me to mention them. In hectic, the third stage of irritative fever, the patient will now require support. He may take any nourishment of a mild description and easy of digestion, and quinine, bark, wine, and porter, &c. may be administered. In conclusion, as a general rule, when local irritation is produced from any particular cause, the removal of that cause will relieve it.

ON INFLAMMATION.

To the Editor of the Medical Gazette.

SIR,

THE appearance of the Encyclopædias of Practical Medicine and Surgery may be regarded as marking an era in medical literature. Contemporaneous periodicals, ever ready to praise and be civil to those who do not need it, look on approvingly, occasionally patting on the back some of the gentlemen who so complacently sign their names to their monographs, and who thus register themselves among the *patres conscripti* of medicine and surgery; so that our immediate as well as more remote successors, who would refer to them as affording evidence of the manner in which these works were received by the profession, will find no reason to doubt that they gave a fair and faithful digest of the state of medical knowledge as actually existing at the date of their publication. I would not venture on light grounds to disturb all this harmony, but I have been for many years an attentive observer and collector of facts bearing upon the grand centre of all medical science, namely, the doctrines of inflammation; I have noticed the controversies and discussions to which these facts have given rise, and I have also noticed with pain the reproaches which, on account of the unsatisfactory state of these doctrines, have from time to time been cast upon medical science. I feel, moreover, that this stigma will not easily be removed, so long as the works above alluded to are permitted to spread through the length and breadth of the land without one word of warning or caution against the fallacy of the doctrines they contain on this all important question. In the absence, therefore, of any one either more capable or more unwilling, I venture to take part of your motto to myself, and say "*licet etiam mihi dignitatem artis medicæ tueri*," satisfied that a complete reform in the doctrines of inflammation, and, as a necessary consequence, in those of fever also, will do more to oppose the marauding incursions of the light cavalry of quacks, than all the charters that can possibly emanate from royal authority; because the elevation of the study of diseases to its proper position

as a science will inspire public confidence.

Every one knows that the great mass of facts resulting from the accumulated researches of various and numerous individuals, and bearing upon the subject of inflammation, have been discovered since the death of Mr. Hunter. As all these inquirers undertook their investigations with the express view of examining the actual condition of the blood-vessels and tissues while in the state of inflammation, and as every inquirer is always more prone to favour the inferences drawn from his own performances, more than those either of his rivals or his predecessors, it is by no means wonderful that much discussion should have arisen, and great contrariety of opinion should prevail, on this fundamental point. If Mr. Hunter had left this point in a satisfactory condition, there would have been no occasion for any further information; but that he did not do so, the simple fact of so many individuals, unconnected with each other, having instituted their investigations, and persevered in them for years, may be taken as proof enough; indeed, it must be confessed that the labours of Mr. Hunter in this respect can scarcely be considered as worth mentioning in comparison with what has been done since his time. If, on the one hand, a comprehensive glance be cast over the very few data respecting the changes which occur in inflamed parts in Mr. Hunter's possession, and the wide reach of his doctrines, extending to every possible variety and degree of inflammation; and, on the other, over the vast store of positive facts accumulated during the last thirty years, of which little or no practical application has been made, we see, in the first instance, surprising activity with most scanty means; and, in the second, wonderful inactivity with most ample means. It is perhaps as well that men's minds should be gradually familiarized with these as yet newly discovered facts; they may possibly apply them more readily to their legitimate use when the proper time arrives; but it has for some years been a matter of profound astonishment, to me at least, that no one, out of all those who have devoted so much attention to the subject, has had sufficient penetration to perceive the bearing which these new facts have

upon every branch of the doctrines of inflammation, as handed down to us from Mr. Hunter, and, as a necessary consequence, upon its treatment too. Many of these experimenters have been very sensible men, and yet the bare suspicion of the idea that so many new facts must necessarily involve new doctrines and treatment, or at any rate an entire remodification of both, never seems to have crossed the minds of any of them; but, on the contrary, as each individual has come forward in succession, after some little difficulty at starting, in torturing his experiments and inferences so as to square with the prevailing doctrines, he tails off in Mr. Hunter's track with the most edifying unanimity. Each man, therefore, has a point of agreement in common with all, viz. an unsuspecting faith in Mr. Hunter's doctrines, and also another point in which he is at variance with each separately, viz. an implicit confidence in the correctness of his own facts and inferences. The labour of all is the same, viz. that of making their opinions eventually square with those of Mr. Hunter, so as to form one *harmonious* (!) whole. The doctrines respecting the distinction between active and passive inflammation appear to have constituted the great stumbling-block over which all have fallen, one after another; but I must not go any farther in this direction, as my present object is not to point out what is right, so much as to show what is wrong: no one is thankful for being told what is true, until he has been fully convinced that what he has hitherto believed is false.

In an Encyclopædia of Practical Surgery, a great deal of what is valuable and excellent respecting the best method of treating fractures, of reducing dislocations, of tying blood-vessels, &c. &c., may be laid down without any regard to the views which may be taken of the nature and pathology of inflammation; but the case is very different in an encyclopædia or dictionary of practical medicine. Here, the doctrines on this subject constitute the life and soul, and pervade almost every part; any serious error or oversight, therefore, in this particular point, is absolutely fatal to the whole work; it ceases to possess any value whatever from the moment the mistake is pointed out. It becomes like a building affected with the dry rot, which requires no rude assaults of

stormy winds for its destruction, but crumbles to pieces of itself, because its principle of cohesion has perished.

It will, perhaps, be better to begin with the examination of Dr. James Copland's views on the pathology of inflammation, as propounded in his Dictionary; not because his opinions are supported with more or less ability than those in the Encyclopædias, but because he boldly asserts his exclusive right to them, and claims great credit to himself on the score of their originality, and also because the sole responsibility rests with him.

In the article on Inflammation, after discussing the more obvious conditions of pain, redness, heat, swelling, &c. &c., incidental to that state, Dr. Copland proceeds to give an account of the causes and rationale of all these phenomena. In paragraph 150, he commences this part of the subject by saying, "The organic nervous tissue is primarily affected in the seat of inflammations of all kinds. I have already contended that inflammation, in its more *sthenic forms*, is a result of a *morbidly* excited state of the organic nervous tissue surrounding the extreme vessels or capillaries of the affected part, or a derangement from an unnaturally exalted condition of these nerves, on which the function of these vessels, and, indeed, of the whole vascular system, have been shown to depend." The correctness of this statement depends on the truth of Dr. Copland's opinions respecting the functions of the nerves. We must therefore turn to the article on Irritability. Here we find him saying, "that the organic or ganglial nervous system presides over the strictly vital functions, and that all the grades and manifestations of irritability or contractility proceed from this source." By this Dr. Copland means, that the power of contracting possessed by all voluntary muscles is not derived from the cerebro-spinal, but "from the organic or ganglial system of nerves—that this latter system bestows on muscular or fibrous tissues the power of contraction, whilst the spinal nerves simply conduct or convey the stimuli to contraction." I must beg particular attention to this point, because these inferences form the key of Dr. Copland's whole position. He examines certain animals whose nervous systems are either chiefly or altogether

ganglionic, and finds that in them these nerves are distributed to every part of the body, and then he concludes that the same arrangement exists in man, and in the higher orders of warm-blooded animals. Are we, then, like polypes, to whom being cut in half is not a matter of much importance? Surely, in order to maintain something like an appearance of probability, Dr. Copland ought to be able to show that warm-blooded animals can live at least as long as frogs after the removal of their brains. When we observe a broad distinction between the arrangement of the nervous systems in the two classes of warm and cold-blooded animals, and an equally well-marked difference respecting their tenacity of life on the receipt of injuries, there ought not to be any difficulty in arriving at the true explanation of the phenomena presented by each. There would, indeed, be some real ground for perplexity if the facts were reversed: but what is the fact? What does anatomy say on this point? All modern anatomists (without any exception, I believe) notice the distribution of ganglial nerves, together with the blood-vessels, to all the thoracic and abdominal viscera, and, in short, to all parts concerned in maintaining what is understood by the term organic life; but nothing is said respecting the existence of ganglial nerves in that large division of the body consisting chiefly of the simply voluntary muscles. It is scarcely possible to conceive that minute dissection can be carried further than it has been: the cerebro-spinal nerves have been traced to their ultimate distribution, in the form of loops, in the voluntary muscles; but no mention is made of any ganglial nerves in these parts, or as to their accompanying the arteries which supply them. So much for the fact. Let us now ascertain whether analogy is at all in Dr. Copland's favour, since he may argue that ganglial nerves may possibly accompany the brachial artery through its whole course without being visible. Now there is no fact better established than this; viz. that the ganglia belonging to the sympathetic are never at any great distance from the parts supplied by them. This is so constantly and invariably the case, that when it becomes necessary to detach a few filaments, as it were, to an out-post, a ganglion is always found; thus, we

never fail to find the sphenopalatine, the lenticular, and the otic ganglia, in their proper places. These examples are not numerous, but they are most significant, as leading to the inference, that, if the ganglial nerves were distributed to the limbs and general frame of the body, the ganglia themselves would be found there also; and that, not so small as to be discovered with difficulty, but so large that there could be no mistake as to their nature: for, be it remembered, there is no difficulty in finding them in those animals whose nerves are entirely ganglionic.

Much more might be urged most effectively on this point; but I feel constrained to be as brief as possible, and I think enough has been advanced to prove that Dr. Copland has drawn, and relied upon, a false inference; that, being unsupported by fact, and contradicted by analogy, he has no ground whatever for concluding that ganglial nerves exist in parts where they cannot be demonstrated by the most minute dissection. The key-stone of his position being thus not merely loosened, but completely removed, the whole superstructure necessarily falls to the ground.

“*Celsæ graviore casu
Decidunt turres.*”

Dr. Copland is by no means singular in this mistake, of supposing the ganglial nerves to be distributed to every part of the bodies of warm-blooded animals; Dr. Wilson Philip, among others has fallen into the same error; but I believe that all who have adopted this opinion are *physicians*; that is to say, men who cannot be received as authorities on an *anatomical* question.

I may, perhaps, be excused for noticing in this place a most reprehensible and pernicious method of induction, which has obtained of late years, more particularly among those who are fond of making experiments, and of drawing their illustrations from comparative anatomy. These gentlemen employ themselves in ascertaining in what class of animals any given system or organ exists in the most simple or rudimentary state, and in tracing its gradations successively through the lower classes up to the highest; and having done this they allow themselves to reason in the same direction; that is, from below upwards. They examine

thus, for example, all the varieties of the sanguiferous system, and because they find the circulation carried on in some without the aid of a heart, they infer that it is maintained chiefly by means of the capillaries in those where the mechanism of this organ is presented to us in its most perfect form, and consequently that their powerful muscular apparatus is only of inferior or secondary importance; and yet there is no fact more clearly established than this, viz. that the force exerted by the heart is capable of overcoming, and does actually overcome, at every stroke, the resistance occasioned by the elastic pressure of the whole arterial system. We see this most fallacious method of induction gravely adopted by physicians who are well acquainted with the dreadful distress, in fact the painful struggle for existence, which is attendant upon any disease of the heart, which impairs the efficiency of its action. It appears to me, that the only true inference to be drawn from a general glance at the various modes by which a circulation is accomplished in different classes of animals, is this; that a circulation is necessary to all, and that this common object is attained by a *variety of means*, some of which we can understand, but others are beyond our comprehension. It has become the fashion to argue from what is not known in direct contradiction to what is well established, and I suppose it will continue so for a time, although it is not possible for arguments so derived to lead anything but error. It is unnecessary on this occasion to point out what errors spring out of the original one, with regard to the universal distribution of the ganglial nerves, or to trace the mode in which it extends its baneful influence like a subtle poison throughout the doctrines contained in the Dictionary of Practical Medicine: I will, therefore, conclude for the present and remain,

Your obedient servant,
J. W. EARLE.

Cheltenham, March 6, 1844.

THE BATH WATERS.

To the Editor of the Medical Gazette.

SIR,
A FEW months since you inserted in your journal a statement from Sir

Alexander Crichton, in commendation of the thermal waters of Bath, from the use of which that justly esteemed and veteran physician had derived great and manifest benefit, on two different occasions, whilst labouring under disease.

Communications such as that (and from such a quarter), purely practical, and irrespective of any theory, tend more to the advancement of the healing art than any of your finely spun chemico-medical, or medico-physiological, or even electro-chemico-mechanical speculations, into which our profession seems about to fall, after a long season of purely empirical practice.

When a physician grown grey in the exercise of his profession, himself a sufferer, tries, either from a spontaneous conviction of the propriety of such experiments, or at the instigation of those who are best conversant with them, the effect of thermal springs in his own case; and, in due season, tells his brethren that, through those means, and those only, his health was restored at two distinct times, after every other method of treatment had failed, we derive great encouragement from his example: we feel no hesitation in recommending it to be followed by other patients placed under similar circumstances, and we enhance the value of the means employed by publishing the successful results.

These considerations have induced me to request your insertion of the following brief narrative of as effectual a cure, produced by the Bath waters on myself, as that related by Sir Alexander. Thus will the public learn, through your channel, that, in recommending to others, in the earnest manner I have done, in the second volume of the *Spas of England*, the unjustly neglected volcanic springs of Bath in certain complaints, I so far yielded to the dictates of my own conscientious belief in the virtues I practically knew them to possess, that when the necessity for trying their effect on myself unfortunately did occur, I hesitated not a moment in doing so, fully impressed with the notion that no other means were likely to restore my health so quickly.

The treatment of chronic, and, in many cases, of recent disease also, by mineral waters, seems to be so directly prompted by the bounteous dispensation of the Creator, who has laid those

wonderfully constituted agents, in more or less profusion, within the reach of every nation, that, during the repeated and successful endeavours I have made, in the course of many years' experience, to recal public attention, in this country, to the importance, and superior as well as pleasanter nature, of that treatment, I considered myself to have been the humble instrument of His providence. Most assuredly His benevolent views, in vouchsafing such a blessing (for I cannot look upon mineral springs in any other light), will never be thwarted by the malice and scoffing of plagiarist writers or interested critics, who, under the garb of pretended eulogiums, struggle to put down, by sneers and doubts, the reviving popularity of mineral waters.

I am, sir,

Your obedient servant,

A. B. GRANVILLE,
M.D. F.R.S.

109, Piccadilly, March 6th, 1844.

NARRATIVE.—On the 5th of October last, being then in my usually good state of health, as I was returning to town, from a long walk into the country, I found, at the end of my path, a narrow and shallow ditch, across which I leaped. Unfortunately I took my jump with closed knees, and alighted on the opposite side on both my heels at the same instant, with the body nearly erect. The result was a sudden and most distressing jerk, which shook my whole frame, from the loins up to the back of my head, and, for a moment, made it doubtful whether I should be able to proceed farther.

After staggering for a few seconds, and pressing my hand on the left side of my chest, where I likewise experienced some uneasiness, I felt equal to walk again, though not with the same freedom and elasticity as before. There were no public conveyances at hand; and I had to make my way back to town, the distance of six miles, the best way I could.

Not to enter into particulars which do not directly bear on the single point of my present communication, I shall merely observe that, from the day of the accident until a few days after my arrival at Bath, in the second week of December, a period of ten weeks, I never could change from the horizontal to the erect posture, or attempt a few steps across the floor,

without experiencing the most distressing symptoms; unaccompanied, however, by any pain whatever, as long as I remained perfectly quiet in a recumbent or semi-recumbent posture, or even sitting. Not the slightest indication of disturbed health was perceivable.

The distressing symptoms I allude to were, first, a feeling in the right inguinal region and hip as if the limb were severed from the body, or did not belong to it; next to which came a sense of constriction at the precordia; to which, if I persisted in my progression forward, succeeded great anxiety, a flushing of the face, and a sense of fulness at the back of the head, when I found it absolutely necessary to stop, and immediately to lie down. On two or three occasions I thought I experienced some giddiness also; but this might have been only apprehension, as I admit I felt very nervous at the obstinacy with which the same disabling effects invariably followed every attempt at walking, except in walking up and down stairs, when no disagreeable effect ever occurred.

These symptoms did not seem to depend on any real injury done to the spine, or to the right hip-joint, from which latter part, as I before remarked, they appeared to take their origin, extending thence upwards to the back of the head, and downwards to the front part of the right leg. This point was clearly made out by my own observations, and those of Sir Benjamin Brodie, who kindly paid me three or four visits after I had been confined to the house about five weeks, and carefully examined the parts, in which he could not detect the smallest lesion. He agreed with me and the two medical friends who had been endeavouring to find out and remedy the cause of my complaint, that it was a singular case of nervous affection, produced by concussion, and thought that some considerable time would elapse before I could again walk with impunity. He therefore recommended rest above all things; and, as my general health was not otherwise much impaired, he abstained from ordering any medicines.

The anomaly of the case consisted in this,—that although I could not walk without producing such general

distressing symptoms as I have described, *beginning always in the right extremity*, the power of action, the feeling, the agility and strength, as well as the warmth, colour, and size, of the affected limb, were in their perfectly normal state; and, in fact, offered not the smallest vestige of difference between it and those of the corresponding extremity of the left side.

This state of things lasted, as I before stated, ten weeks, during which period I more than once resolved on losing blood—once (on the outset) by venesection, thrice afterwards by leeches, and as many times by cupping. For these several abstractions of blood, which were never to any great amount, but which, I feel convinced, were useful to me, I am alone responsible. I could not divest myself of the notion that some venous congestion had been the result of the concussion I had experienced during the leap I took; and some singing in my left ear, to which I had never been subject before, but which had existed since the accident, and was always relieved after bleeding, confirmed me in that notion. I ought to add, however, that I never was drowsy in the least; that I experienced no interruption in my ordinary sleep at night; and that the pupils of my eyes had never deviated from their natural state. Indeed, so far was I from being otherwise ill, that I carried on, for an hour or two every day, my usual written correspondence, and was able to attend to professional consultations in my room, provided I did not move. The low diet on which I deemed it prudent to live for several weeks, and the daily use of aperient medicines, together with the total suspension of my ordinary very active habits of life, had certainly produced great general debility, and given me the appearance of one in very bad health.

In this state, and discouraged at the only alternative of having to remain in a state of inaction for an indefinite period, I determined at once to proceed to Bath, to try the effect of those thermal springs on my limb. The result was, beyond my expectations, favourable; nor was the rapid manner in which that result was brought about less surprising. Hardly able, when I arrived in that fair City of the Waters, to walk from the railway station to the carriage, and being made ill during the

first four or five days of my *séjour* in that most excellent and well-appointed hotel, the York House, by a mere walk of eighty paces between the bed and the sitting rooms on the same floor, by the time I had taken fifteen baths, and had applied the *wet douche* to the whole length of the affected limb ten successive times, I found myself equal to walk from York House to the bottom of Wilson Street, and back again, a distance of more than a quarter of a mile, without experiencing any inconvenience whatever.

From day to day, and from the very first half-dozen baths, I became sensible that a manifest improvement was taking place in me; and subsequent experience has convinced me that to the application of their peculiar agency to my disabled nerves I am indebted for my present perfect recovery. The employment of ordinary warm baths had been previously tried every day, for some weeks, in town, to no purpose: to deny, therefore, the direct influence of the thermal springs in effecting the complete restoration of my limb and good health, would be to fly in the face of the most palpable evidence.

In conclusion, I have only to add that I have continued in perfect health ever since; and that the almost sudden transition from absolute confinement in the house during the whole of the last three months of the year, to the entire and unlimited exercise of my profession and usual active habits—in doors and out of doors—to which I have been restored by the Bath waters since the beginning of January last, would appear to me almost miraculous, were I not, from extended experience in matters of this kind, aware of a very large number of cases of recovery, equally surprising, having been effected by what I have called, in my works, "*telluric heat*," diffused through mineral waters.

URINARY DEPOSITS.

To the Editor of the Medical Gazette.

SIR,

HAVING perused the communication of Dr. Ward, in the last number of your valuable GAZETTE, and having frequently met with cases similar, in some respects at least, to the one therein related, I have forwarded the present remarks, with a view of affording some

facility in the recognition of the nature of the deposit therein described, as well as of urinary deposits in general.

I am, sir,

Your obedient servant,

J. W. GRIFFITH, M.D. F.L.S.

9, St. John's Square,
March 4, 1844.

I am sorry to find that the milky or oleaginous character of the urine, in the cited case, was not recognized by other means than the mere microscopic examination; and this for several reasons. One is, that it is an extremely difficult matter, and requires great practice, to be enabled to distinguish quantity by the microscope: hence, to those but little accustomed to such investigations, a very small quantity of a substance whose presence is ascertained is apt to receive great attention, and its importance be overrated;—another is, that a description of the mere microscopic appearance generally serves more to excite the imagination than to assist in developing the real nature of a substance. The application of a few tests, in the case alluded to, would have determined in one minute the true nature of the crystalline matter with positive certainty; and if there is any use in recording the particulars of cases, it must certainly be better to report them in a positive and satisfactory manner, than to leave them in a state of doubt and uncertainty.

The deposit described by Dr. Ward in all probability consisted of either lithic acid or lithate of soda; such, at least, I should imagine from the description; although the size of the crystals is not mentioned, nor their colour*: moreover, if they really were lithic acid, they would have been dissolved by nitric acid, which appears not to have been the case; but probably nitric acid was added to them whilst immersed in the urine; thus, by becoming diluted, its action would be that of dilute nitric acid, which does not act nearly so much upon either lithic acid or the lithate of soda as the concentrated. Both lithic acid and lithate of soda are very frequent in the urine of children affected with scarlatal anasarca, as I have very frequently had opportunities of proving. In fact, these are the only cases in

* "The spikes, resembling splinters of glass," (and which were probably colourless) were most likely the super-lithate, for lithic acid never exists in a colourless state in the urine.

which I ever recollect having found the urate of soda in a crystalline state. They are frequently mixed with lithate of ammonia, also in a crystalline state; and the two deposits much resemble each other. The latter has been figured from one of my specimens, in a sketch accompanying the valuable lectures given by my friend Dr. G. Bird. I was at first inclined to the belief that the crystalline needles found upon the surface of the spherical centres might be distinguished by their acuteness in the lithate of soda, and their obtuseness in the lithate of ammonia; such, however, I have not found verified. In fact, when lithate of ammonia is prepared artificially, by decomposing a solution of lithate of potash or soda by muriate of ammonia, the lithate of ammonia is precipitated in a crystalline form, and retains partly the microscopical characters described by Dr. Ward. Is this the manner in which this deposit, when crystalline, is formed in the human body? The acicular crystals found on the surface of the central globules of lithate of ammonia and soda, when crystallized, have been usually considered as being composed of superlithate; this, however, I believe to be incorrect, for I have distinctly crystallized the lithate of soda (both the central spherules and radiating needles) from an alkaline solution of this salt.

In the treatment of scarlatinal anasarca, the plan I have always found most beneficial is that usually recommended by the best authors, viz. that of depletion, carefully avoiding squills, or all active diuretics, which are, doubtless, as improper in that disease as are stimulating expectorants in the bronchial affection attendant upon measles. The best treatment is occasionally venesection, (which, however, is not often requisite,) antimonials in free doses, hydragogue purgatives, warm baths, &c.

In the course of the last summer I found a very curious deposit in the urine of a female patient, about fifty years of age, under my care at the Northern Dispensary, who had suffered from severe pains in the jaws, and whose gums were extremely vascular, having arisen without any apparent cause. There was no tendency to hæmorrhage from any part of the body; the patient was debilitated from attending to her husband, who had been extremely ill; she had also pro-

lapsed uteri, dyspepsia, &c. The only remedy I found of any service to the gums was the application of nitrate of silver in very strong solution. Leeches to the jaws, aperients, tonics, (mineral and vegetable) astringents, creasote, and a host of other remedies were unavailing, although long and steadily continued. There were no urinary symptoms, except slight irritability of the bladder. The urine was pale, slightly but distinctly acid (sp. gr. 1016), containing an increased quantity of mucus, but of the healthy kind. The deposit was white, crystalline, and opaque, like phosphate of lime to the naked eye. When examined by the microscope, it was found to consist of nuclei, which were almost colourless, and studded with minute acicular crystals all over their surfaces. It was well washed with water, and dried. It was soluble in diluted acids with copious effervescence, the solution being precipitated by oxalate of ammonia. When heated to redness, it left a white, alkaline, infusible ash: this was soluble in diluted nitric acid. The solution gave a white precipitate with oxalate of ammonia. On its solution in dilute nitric acid and evaporation, no trace of lithic acid was present, nor was phosphate of silver precipitated when solution of the nitrate was added. This deposit was thus clearly shown to consist of carbonate of lime in the crystallized state. Its examination was also made by my friend Mr. W. Francis, who arrived at exactly the same results. I found it several times in this urine, which in other respects was natural, and distinctly acid, and thus was not the result of the decomposition of urea, and consequent precipitation of the calcareous salts by the ammoniacal carbonate formed. Carbonate of lime is, I believe, never found in the urine, except under the last mentioned circumstances, and I also feel convinced that carbonate of ammonia is never found in that fluid, except as a result of decomposition, for in all the cases where it was supposed to have been *secreted* there has been a marked degenerated state of the fluids of the body, such as predisposes them to rapid decomposition; and any one who has paid much attention to the study of the urine knows well how very rapidly the urine becomes alkaline under certain circumstances.

I may remark, that some artificially

crystallized carbonate of lime, which I be wondered how a carbonate can prepared, almost exactly resembled the exist in an acid urine undissolved? and nucleated part of this deposit. It may I confess it has always puzzled me to

Effects of reagents upon urinary deposits: the characters in the first columns, combined with the microscopic appearances, will serve to distinguish one from the other, and, being readily applied, will be sufficient for the use of those who have not opportunities for their minute investigation.

Name of Deposit.	Ordinary Colour.	How Affected by				Blowpipe upon Platinum Foil.	Characteristics.
		Boiling Water.	Sol. of Ammon.	Sol. of Potassa.	Acetic Acid.		
Lithic acid	Yellowish-brown	0*	0†	Dissolved	0	Dissipates it entirely	When evaporated to dryness with dilute nitric acid and ammonia subsequently added, a pink colour is developed.
Lithate of ammonia‡	Whitish, pink, brown, & red-brown	Dissolved	Instantly dissolved	Idem	0§	Idem .	Idem.
Phosph. of lime	White, amorphous	0	0	0	Is dissolved without effervescence	Unaltered	Nitrate of silver causes a yellow precipitate in the acetic solution, which is also precipitated by oxalate of ammonia.
Ammonia - co-magnesian phosphate	White, generally crystalline	0	0	0 The odour of ammonia is evolved by heat	Is dissolved without effervescence	Ammonia is evolved, otherwise unaltered	Nitrate of silver precipitates the acetic solution yellow; this, however, is not precipitated by oxalate of ammonia.
Oxalate of lime	White, generally crystalline	0	0	0	0	Leaves an alkaline ash, which efferv. with, and dissolves in, dilute muriatic acid	The solution is precipitated by oxalate of ammonia.
Cystic oxide	White, bluish, or greenish	0	Is dissolved	Is dissolved	0	Entirely dissipated	Crystallizes from the ammoniacal solution on evaporation. When boiled with hydrated oxide of lead, the black sulphuret is formed.
Carbon. of lime	White	0	0	0	Is dissolved with effervescence.	Leaves an alkaline ash	This ash is soluble in acetic acid, and the solution precipitated by oxalate of ammonia.

* 0 signifies no effect.

† Those effects which take place at once or within a few minutes only are noticed.

‡ When lithate of soda is present, the reagents mentioned act much more slowly and imperfectly.

§ Acetic acid decomposes lithate of ammonia, and throws down the lithic acid, so that one deposit occupies the place of the other, and no apparent change occurs.

|| If lithates of soda or lime are present an alkaline ash is left.

explain such an occurrence. However, I cannot, with some others to whom I have mentioned this circumstance, throw it aside because I am unable to explain its cause. The only explanation I can offer is, that probably it was secreted and retained in a state of solution by carbonic acid, and as this escaped the deposit assumed this form. I did not examine the urine with this view at the time, for the deposit was only discovered by accident some time after the patient had been under my care, and I have never since then met with her. Carbonic acid has been found in the urine dissolving the phosphates in this manner, which have become precipitated by heat, or on exposure to air; and such I imagine must have been the case here. I subjoin a tabular arrangement of the characters of the deposits found in the urine [see p. 830]; the microscopic appearances have been illustrated in the lectures by Dr. Golding Bird, in former numbers of this journal, which, combined with this table, will remove any difficulty in at once recognizing any deposit.

Blood is recognized by the colour it imparts to the urine being destroyed by boiling: the solution then becoming colourless or yellowish, the clot of a chocolate colour; also the microscopic appearance of the globules in the sediment.

Semen is recognized by the increased mucous cloud, (not always apparent, however); the urine is also albuminous. The best evidence is the presence of the spermatozoa; the odour is perfectly valueless. In every case where albumen is present in the urine of a male patient in small quantity, examine the deposit to ascertain if such be caused by the presence of semen.

Pus is recognized by its forming a yellow layer or deposit, which, if mixed with lithate of ammonia, occupies the lowest position, the lithate forming a stratum above it, generally well contrasted by its pink or reddish colour. The urine is albuminous; the deposit is readily diffused through the urine, and has no viscidty or tenacity, but acquires this when mixed with ammonia. The presence of the numerous globules, which have been so frequently described, and the albuminous supernatant liquor, are necessary for the recognition of pus; the one can be depended upon without the other.

Mucus is recognized by its viscidty, tenacity, and glairy characters; the supernatant liquid is not albuminous; the layer formed by mucus in urine is always higher and much less dense than that of pus; moreover, it is not diffusible through the urine like the former; globules quite as perfect, both as regards nuclei, and in other respects, are found in mucus, often acted upon with more difficulty by reagents, as acetic acid, &c. inasmuch as they are enveloped in a gelatinous mass, which temporarily defends them.

For further particulars on the characters and microscopy of this subject, I refer the reader to my "Manual on the Characters of the Blood and various Secretions of the Body," wherein the requisite information on this subject will be found.

TREATMENT OF CHOLERA.

(For the Medical Gazette.)

(Extract of a letter to the Bengal Medical Board, dated 27th December, 1843.)

General Hospital, Calcutta.

SIR,

IN continuation of my letter of the 15th of September last, to your address, I have the honour herewith to transmit copies of two cases of cholera treated on principles adapted to my ideas of the nature of that disease, as explained in the letter above alluded to.

Under a total cessation of the powers of absorption by the internal surface, it is manifest that little or nothing can be hoped from the internal administration of even the most powerful remedies, and that such is the case in this formidable disease, the experience of the past seven-and-twenty years affords abundant and melancholy proof.

With this impression—I may say with the conviction, that this is the true cause of the utter powerlessness of medicines in cholera, which if given in similar doses in any other disease could scarcely fail to prove destructive—I have lately ventured to adopt a practice in favour of which I have long had a prejudice, viz. the use of long-continued hot baths, during the stage of collapse; not the commonly prescribed hot baths of authors, of from 98° to 104°, and continued only from ten to fifteen minutes, but a bath

of 110° to 115° Farht., and continued for a full hour, or more, according to circumstances, until the restored circulation indicates the removal of that obstruction on which I conceive collapse, in cholera, to depend.

So novel a prescription will doubtless be received with hesitation, possibly with alarm, and did the collapse result from long previous illness, or extreme exhaustion, its application might well be expected to produce, perhaps, fatal syncope; but in cholera the case is difficult: the invasion of the disease is sudden, the patient frequently in high health only a few hours before; and the copious sweats and ejection of chyle (forming, in a dilute state, the characteristic "rice-water" evacuation of cholera) the only visible causes of exhaustion. The disease being sudden and rapid in its progress, it is obvious that the remedy must be powerful and sudden in its action, or a fatal termination, as is too generally the case, be the result.

Thus much in support of a plan of treatment, which, however, the very appearance of the patient serves strongly to indicate, but which will be much better supported by the cases accompanying: and I beg particularly to call the attention of the Board to that of Samuel Brown, who, at 10½ P.M. was evidently relapsing, but again restored by a full hour in the bath (at 110°); declaring, when replaced in bed, that he felt "like a king;" and I had the pleasure next morning to find him comfortable, with a warm skin and soft steady pulse, while two poor fellows, the one admitted an hour before, the other an hour after him into the opposite ward, were being carried out to the dead-house.

I have merely to observe, in conclusion, that these are the only two European cases that I have had an opportunity of treating for some months.—I am, sir,

Your obedient servant,

C. W. RANKIN.

N.B. The cases of spasmodic cholera I have alluded to were treated by hot baths, drastic purgatives (daily), and blisters to the nape on the occurrence of delirium, with ice to the head, and occasionally four and six leeches to the temples.

CASE OF THE SUCCESSFUL REMOVAL

OF A LARGE OVARIAN TUMOR.

By DR. FREDERIC BIRD,

Consulting Accoucheur to the Western Dispensary, Physician to the Metropolitan Hospital and to the Westminster Maternity Charity, and Lecturer on Medical Jurisprudence at the Westminster Hospital.

(For the Medical Gazette.)

On December 28th, I was requested to meet Mr. Hale Thomson, in consultation on the case of Mrs. —, residing in — Terrace, Regent's Park, who had long been the subject of a large abdominal tumor. She had just completed her thirty-fifth year; and, until the occurrence of her present malady, had enjoyed previous good health. The catamenial function, developed at the age of thirteen, had, after the lapse of ten years, become irregular, the secretion having been deficient and accompanied by severe dysmenorrhœa. From the pain of the latter she has since continued to suffer; but has also, during the last two years, experienced the frequent occurrence of menorrhagia. She has never borne children, but believes that abortion at a very early period of gestation once took place. About six years ago, after having made some slight, but sudden, muscular exertion, she was attacked with acute pain affecting the right side of the abdomen, midway between the false ribs and crest of the ilium; a distinct swelling at this part having been observed by the medical attendant. In a few days the pain subsided; and in as many weeks the tumefaction also disappeared. Mr. H. Thomson, who was consulted at this period, discovered a small tumor occupying the seat of pain; and on several subsequent occasions was also able to detect it. Notwithstanding the existence of disease, her general health suffered no impairment until the commencement of the past year, when she began to lose strength rapidly, and soon afterwards observed that her abdomen increased in size, the enlargement taking place at the hypogastrium, and did not at first involve either iliac region. Menstruation continued painful, but became menorrhagic; nevertheless, pregnancy

was said to exist, although every indication of gestation, save abdominal enlargement, was wanting. The term of pregnancy expired, and was followed by the more rapid growth of the tumor, and greater deterioration of health. She was at this time seen by an accoucheur of eminence, who at once pronounced her to be labouring under ovarian dropsy. The tumor subsequently increased in size more rapidly than before; and the impairment of health, probably favoured by the mental distress consequent upon the discovery of her unhappy position, became more evident. She began to suffer from almost constant nausea, and frequent vomiting; whilst obstinate diarrhœa, impeding respiration, occasional accessions of fever, and general emaciation, made up the sum of symptoms.

At the period at which I was requested to see her, the abdomen was much and equally distended, slightly retracted at the lumbar regions, but very prominent above the pubis and at the umbilicus; the integuments were tense and smooth, striated longitudinally by many turgid but small veins, and transversely by lineæ albicantes: the total circumference was forty inches. Percussion elicited an uniform dull sound, excepting at the posterior parts of the hypochondria, which were occupied by the tympanitic intestines: the sense of fluctuation was very distinct and equal in every direction; and the most careful manipulation failed to detect the presence of peritoneal adhesions, or of any secondary tumor. The uterus was found small, healthy, very mobile, and had probably never been impregnated. The cavity of the chest was much encroached upon by the tumor, respiration was short and hurried, the action of the heart irritable, and the pulse ranged at 100.

From the consideration of the symptoms presented, there was no difficulty in concurring in the opinion formerly expressed as to the ovarian seat of the disease; and it was obvious that, unless relief were speedily afforded, life could not long continue. Under these circumstances, I suggested the operation for extirpation as the most advisable remedial measure; the attendant dangers, and probabilities of success and failure, being at the same time

fully explained to the patient by Mr. Thomson and myself. Before deciding upon the performance of an operation, subsequent consultations were held, when she had the advantage of the opinions of Dr. Locock and Dr. Hamilton Roe, both of whom accorded in the view previously afforded, and gave their sanction to the measures proposed for her relief.

Twelve days now elapsed, during which time the abdomen increased in circumference two inches, and the general symptoms were becoming more urgent; the diarrhœa was, however, arrested, and no longer presented any obstacle to the operation.

January 28th.—The operation was to-day performed, in the presence of Dr. Locock, Dr. Hamilton Roe, Dr. Merriman, Dr. Andrews, Dr. Hodgkin, Mr. Bransby Cooper, Mr. B. Phillips, Mr. Hale Thomson, Mr. Tomes, and Mr. Parrott, of Clapham. The same preliminary measures having been employed as in my former operations, the patient was placed transversely on the bed, with the feet supported over its side to a convenient height. It was now remarked that the tumor projected more at the left than right iliac region; the sense of fluctuation being as distinct at this as in other parts. A roller was applied around the lower part of the chest, with a view of subsequently affording the support to the diaphragm which would be lost by the removal of the tumor; I then made an exploratory incision, about two inches long, in the course of the linea alba, and a little below the umbilicus. The tumor was, at this point, closely adherent, and its parietes very thin; so that, in opening the peritoneum, the cyst was also punctured: a dark-coloured, firm, but small gelatinous mass, jetted out, and so completely filled up and concealed the aperture, that it appeared as if some secondary growth had formed on the exterior of the tumor. The incision was then enlarged to about four and a half or five inches towards the pubis, the adhesions having been ascertained to be short and general, but yielding to moderate pressure; and it appeared at least very probable that they might be removed without difficulty. Dr. Locock, who also examined them, readily and fully confirmed this opinion; and I then cautiously separated the attach-

ments in the immediate neighbourhood of the wound, and was thus enabled to introduce the flat hand between the abdominal walls and the surface of the tumor: by gentle pressure, the adhesions, which were present over the entire anterior surface of the cyst, were detached, and, excepting in one or two points, with but little difficulty. It was necessary to introduce the opposite hand in order to separate the adhesions on the right side, on which they extended lower than on the left. The great advantage of an incision of moderate size was at this stage of the operation especially observed: the greater part of the abdominal parietes still preserving their tense condition, and the subjacent tumor being as yet undiminished, the adhesions, by the introduction of the hand, became extended, and thus more readily gave way before its pressure. A free incision was next made into the tumor, the edges of which were kept in apposition with those of the external wound, and its bulk much reduced by the withdrawal of a considerable portion of its contents. A firm grasp of the cyst was then made by forceps constructed for that purpose, the abdominal incision elongated to about three inches, and the tumor, in a partially collapsed state, very gently withdrawn from the abdominal cavity, the lips of the incision being most accurately and promptly closed by Mr. Phillips. The pedicle was next secured by three ligatures made to encircle different portions: it was then cut through, and, its vessels having been found effectually secured, returned into the abdomen. The wound was closed by several interrupted sutures, the ends of the ligatures secured, cold water dressing lightly applied, a thin roller of linen drawn once round the abdomen, and the patient moved, by means of a doubled sheet previously placed beneath her, to a more comfortable position in bed.

Scarcely an expression of suffering was uttered by the patient, who, possessed of much moral courage, bore the operation with admirable fortitude. The pulse, at its completion, was observed by Dr. Locoek to be 94, marking an acceleration of only four beats.

$\frac{1}{2}$ past 2 o'clock — one hour and a half after the operation. — Pulse has risen to 100; heat of surface increasing;

neither local pain nor tendency to vomit; sleepless.

R *Liquoris Opii Sedativ.* ʒj.; *Decocti Amyli*, ʒiij. M. *Fiat enema statim injiciendum.* No food allowed. Rough ice to be frequently and freely given.

4 o'clock. — Has not slept, but is quite free from pain; pulse 98; urine removed by catheter ʒviij.

8 o'clock. — Still sleepless; arterial action increased; pulse 110, sharper; respiration equal, but more frequent — 28; six ounces of urine removed by catheter.

11 o'clock. — Dr. Locoek now saw her with me. She had slept half an hour, and was very cheerful and disposed to talk. The pulse still ranged at 110; skin beginning to perspire; tongue natural; urine ʒiv. by catheter.

29th, 2 A.M. — The right side of the abdomen and epigastric region have become distended by flatus; there is some general diffused tenderness on pressure over the whole of the abdomen; heat of surface rather increased; tongue pale; pulse 114, readily compressed, and not contracted. The position in which she lies is not that indicative of peritoneal inflammation; and the local tenderness evinced on pressure may be regarded as the necessary result of irritation consequent upon the detachment of the adhesions, rather than as any evidence of active inflammation. With this view, and for the purpose of assisting in the removal of flatus, she was ordered —

Small quantities of brandy, with hot water, strongly spiced, to be frequently given.

4 A.M. — After a few tea-spoonfuls had been taken, copious eructations followed, the abdomen became much less distended, and she was soon calmly sleeping. Urine ʒviij.

8 A.M. — Has slept at intervals for three hours, and is now almost free from local tenderness and abdominal distension; pulse 108, of good character; skin freely perspiring.

2 P.M. — Dr. Locoek also saw her, and did not hesitate to give a decidedly favourable prognosis. Pulse 108; no abdominal tenderness; skin continues to perspire; the position is easy, countenance good, and spirits excellent.

12 P.M. — With the exception of the pulse having risen to 110, she remains in the same state.

30th, 5 A.M. — Has had three hours'

sleep, and is much improved; pulse 100, soft. The upper portion of the wound has quite united; the lower suppurates healthily.

Vespere.—Visited by Dr. Loeck, at which time there was some slight re-accumulation of flatus in the transverse colon, but quite unaccompanied by local uneasiness. Thirty ounces of urine had been removed at different periods during the day. Skin still perspiring; pulse 98, natural; tongue clean.

31st.—Remains in the same favourable condition. Urine xxviii . during the day.

Allowed four ounces of water-arrow-root.

Feb. 1st.—Slept well throughout the night; pulse the same; urine xxviii .

2d.—Rapidly improving; pulse 84.

Allowed veal broth, with vermicelli, tea, and dry toast. Ice in diminished quantity.

3d.—No alteration. The bowels not having been relieved since the operation, she was ordered—

Olei Olivæ, ʒij . tertia quâque horâ ad quartam vicem.

5th.—The bowels not having acted, she yesterday took the following medicines, which have to-day been followed by copious dark scybalous dejections, partly consisting of fæces long impacted

R Pil. Rhæi Co. gr. viij.; Pil. Hydrarg. gr. iss.; Olei Cassiæ, ʒij . Fiant pilulæ duæ horâ somni sumendæ.

6th.—Ligatures tightened. Pulse remains unaltered. Urine passed voluntarily; less in quantity.

10th.—Since the last report she has quickly improved, and her only complaint has been that of hunger. The bowels act regularly; pulse is now 80, and more full. The diet has been cautiously increased, and now consists of a mutton-chop, one egg, beef-tea, and three glasses of claret daily. The temperature of the room, (85° at the time of the operation), has been gradually reduced, and is now about 65° .

March 2d.—It is needless to relate the subsequent reports, and it will suffice to record that convalescence has proceeded rapidly, and without interruption, to the complete restoration of health. The ligatures were removed on the twenty-sixth day after the operation; the wound has quite healed, and, from the contraction that has taken place in the abdominal walls, its cicatrix

does not measure more than one-half of its original length. The whole appearance of the abdomen is natural, there being no longer any flaccidity of its walls, or corrugation of integument in the neighbourhood of the wound. Under the use of a generous diet, strength has quickly returned. She has for more than a week quitted her room, and has taken long rides in the Park. The bowels act regularly, and the secretions are healthy. The catamenia, previously irregular, and invariably accompanied by dysmenorrhœa, have been twice present since the operation, normal in character, and unassociated with any of her former suffering, and she is now, in all respects, perfectly well.

The dimensions of the abdomen before and subsequently to the operation were—

	Before operation.	After operation.
Circumference of the abdomen . . .	42 inches	24 inches.
From ensiform cartilage to pubis . .	$16\frac{1}{2}$ inches	11 inches.

Description of the tumor.—The total weight of the tumor was 35 pounds; it was of an ovoid form, presenting a marked projection at the part corresponding to the left iliac region, where, also, the cyst was very thin. The external surface was anteriorly covered by layers of false membrane, varying in density and strength; in some parts thin and easily lacerable, in others more tough, and of considerable thickness. Small vessels, in great number, ramified throughout the surface, but arteries of rather large size traversed the interior, more abundantly supplying the pelvic portion of the tumor. The pedicle consisted of the right fallopian tube and broad ligament, and contained one large and two smaller arteries. The secretion contained within the cyst presented a peculiar character, and I am happy in being able to record its description by that eminent pathologist, Dr. Hodgkin.

MY DEAR FRIEND,—I hasten to comply with thy request, by giving thee particulars of some points I have noticed in the ovarian tumor which thou hast removed with such satisfactory and gratifying results.

I leave the dimensions, attachments, &c., for thy own description, having the preparation before thee, and merely ob-

serve that there was one large principal cyst, which appeared to have originated in the ovary itself, the traces of which I observed over a portion of the walls of the sac, somewhat larger than the open hand, where the sac was thick and dense, and marked by one or more traces of the cicatrices produced by the escape of vesicles of De Graefe. In some other parts the walls of the sac were so thin that I imagine a slight force suddenly applied might have ruptured them. Notwithstanding this tenuity, which is probably to be ascribed to the rapidity of growth, this large sac had completely the characters which I have described under the term of serous cysts. There were a few subordinate cysts, which were probably as large as one's fist, but of their precise size I am unable to speak, as they were opened before I examined them.

I was more struck with the appearance of remarkably small transparent, almost vesicular, secondary cysts which studded different parts of the generally smooth internal surface of the principal sac. Their membranes were thin and delicate, easily giving escape to the transparent viscid secretion, which, in its characters, resembled that by which the larger cyst was distended.

Of this secretion I must now say a few words.

It had, in an eminent degree, that consistence which produces the character which I think is termed tremulous, and furnishes the most deceptive semblance of fluctuation. It is a consistence very common to the contents of compound sacs formed in or near the ovary; but I do not remember to have seen it so firm as in the present instance, except in secondary cysts, the contents of the principal sac being generally more or less fluid.

Although there was a great degree of uniformity of consistence through the accumulated mass of secretion, the different parts varied in colour and transparency—some parts being clear, transparent, and colourless; others tinged with diffused transparent red; others streaked with red; others of an amber or wine yellow; and others turbid, or opaque yellowish white. Although there were no perceptible circumscribing membranes, these several characters did not, for the most part, insensibly run into each other, but each tended to assume a roundly-

defined figure, suggesting the idea that, if not the contents of different subordinate cysts, the secretion had taken place in different parts of the sac.

The streaks of red appeared to me to be the result of the extravasation of blood from the walls of the sac, some parts of which were highly vascular, constituting a net-work of distended capillaries. The clearest portions of the secretion when examined with a microscope did not seem to consist of a particled material, but, when viewed in contrast with water, merely exhibited amorphous granular matter. Any distinct particles which it might contain appeared to result from the accidental admixture of the particles characteristic of the coloured portions. The most remarkable of these particles belonged to the secretion where streaked with red. They appeared to be modified blood corpuscles; they had lost their circular figure, and assumed various shapes, either polygonal or elongated, with a great tendency to combination in linear arrangement, more like that of the elliptical particles of bird's blood than the columnar form which the circular particles of perfect human blood are prone to assume. A very common form is that of one particle nearly retaining its circular figure, with two elongated ones attached to it at different and opposite points. To each of these, others were attached in the same direction. I observed several clusters of these particles, which did not consist of a single line of particles, but which were three, four, or more in breadth. I also saw them combined in pairs, and in threes, when they were either polygonal, semicircular, or sectors.

In the turbid portions of the secretion I noticed an infinity of very minute particles, which appeared to be spherical, and although many remained isolated, they seemed to have a tendency to aggregation in small clusters. I observed a very few elongated shapes, suggesting a tendency to the formation of fibrous matter. I did not observe any crystals in the portions which I examined, and I could not discover any of the large nucleated cells, which, though not peculiar to malignant structures, are generally, if not always, to be found in truly fungoid or cancerous matter. Somewhat similar particles are sometimes to be seen in

colloid or gum cancer, to which, in physical characters, the secretion in this case bears a certain resemblance.

My own opinion is, that the adventitious growth in this instance is certainly not malignant, but that it is one of the numerous specimens which justify my adoption of one division of the family of adventitious structures, having the type of compound cysts, to which malignancy, so far as we can fix the meaning of this vague term, does not belong. I have published it as my opinion, which I have not as yet seen cause to alter, that a growth originally not malignant, does not acquire this character by degeneration; but that the additions that subsequent growth may make, may possess this character in one or more of its varieties, which strongly indicates the close relationship of this group, and furnishes the most weighty argument in favour of early and complete removal of the non-malignant examples, in which class many of the ovarian cysts are included.

Thine sincerely,
THOMAS HODGKIN.

To Frederic Bird.

In recording the preceding case, I may briefly refer to one or two points in connection with it, which serve to render it one of the most interesting that has hitherto occurred.

The complete success of the operation, when considered in conjunction with its attendant difficulties, would seem to extend the limits within which it may be advantageously had recourse to. But whilst an inference such as this may be made, the important fact should neither be concealed nor forgotten, that circumstances, and dangers totally unlooked for, and for the previous detection of which medical science has as yet afforded no sufficient data, may present themselves, and render the operation more hazardous as to its performance, and more uncertain as to its result.

With reference to the peritoneal adhesions in this case, it may be briefly said, that there was no evidence of their presence prior to the operation, and the previous history was completely opposed to the idea of antecedent peritonitis. It may, however, be justly questioned whether much importance ought to be attached to the negative evidence afforded by the

previous history on this point: there can be little doubt that peritoneal inflammation does frequently occur in the progress of ovarian disease to a sufficient extent to give rise to the formation of adhesions without being manifested by local pain or other of those symptoms which commonly indicate the existence of serous inflammation. Adhesions being present, should they negative the performance of the operation? Much must necessarily depend upon the extent to which they may exist, and the degree of organization they may have attained. Few would be inclined to commence an operation with the knowledge that adhesions were present, but I believe that it may hereafter be found, that the tumor once removed, the adhesions, or rather that changed condition of peritoneum associated with their production, may to a certain extent favour the recovery of the patient by diminishing the liabilities to inflammation. In the present case much manipulation was unavoidably employed in order to detach the tumor, and the operation was coupled with almost every difficulty that might serve to excite subsequent inflammation, yet has the patient recovered even more speedily than in my former cases, in which no such complications existed. It is at least probable that the non-occurrence of inflammation may be attributed partly to the fact, that the peritoneum, by the deposition of adventitious membranes and concomitant changes, had ceased to preserve in a very perfect manner the character of a serous structure, and was not, therefore, in an equal degree subject to the influence of those causes which in its normal state would have been succeeded by inflammatory action. Should more extended experience hereafter establish the correctness of this view, an important collateral circumstance may be met with in the fact, that although extensive adhesions may be present anteriorly, it has been rarely found that they exist posteriorly, and that the floating viscera, which occupy such relative position with regard to the ovarian tumor, will but seldom be found adherent. Such at least is the result obtained from the examination of a large number of recorded cases, as well as in many dissections that have occurred under my own observation.

ON THE DOUBLE SALTS OF IRON.

To the Editor of the Medical Gazette.

SIR,

I VERY respectfully ask leave to occupy a few pages in the MEDICAL GAZETTE, in order that I may be able effectually to direct attention to the subject of this paper—a subject which has interested, and continues to interest, the medical profession; and respecting which it is not more than true to say, that an anxious desire has been manifested to obtain information. Hitherto, however, the attempts to gratify this desire have been unsuccessful; and such has been the conflicting nature of expressed opinion, that the public mind has become almost chaotic. It is no easy task to reduce irregularity to order; and I would not be too confident of my ability to accomplish it in this instance. I am the rather diffident, because, whether I look amongst the advocates of chemistry or pharmacy, those who are remarkable for learning and intelligence forbear to make comment: nevertheless, such as I have I modestly submit; and if I subvert but one error—if I give any information that can be turned to a practical account, or if I put others in the way of arriving at that truth which I may have vainly sought for—I am content.

The opinions I entertain will appear in the course of remarks I purpose making on the combinations of the oxides of iron with some organic acids; and these will be regarded with a view chiefly to determine the nature of certain salts called—

Citrate of iron.

Ammonio-citrate of iron.

Ferro-citrate of ammonia.

A short historical sketch of the progress of discovery connected with the matter before us will form a suitable introduction.

Previous to the year 1830 or 1831, the only salts of iron with organic acids which medical practitioners had recourse to, were the acetate and potassio-tartrate, few in number, and these inelegant. Monsieur Beral, of Paris (taking advantage of Soubeiran's application of the hydrated sesquioxide of iron to the purposes of pharmaceutical chemistry), entered on a course of lengthened experiments in the hope of detecting some combination which

should have stronger claims upon public attention; and, as the result of these endeavours, he offered to the notice of the medical men of France several new salts, and in particular one which he termed citrate of iron: he published also a formula for its preparation; but this formula differed so much from that used in his own laboratory that, in following its directions, an *insoluble* and *acid*, in the stead of a *soluble* and *neutral*, salt was produced. This was a skilful trick of the inventors, whereby he, for a time, kept its preparation to himself*.

Mr. Aikin, in England, some years back (the precise time is not material) introduced an ammonio-tartrate of iron, and it was employed with beneficial results in practice. This gentleman also pointed out the existence of other compounds, which attracted less notice than they deserved, and fell into disuse.

A new method of preparing the potassio-tartrate of iron, suggested by Soubeiran, and improved, I believe, by Mr. Phillips, was published in the last edition of the London Pharmacopœia.

About two years since, a "citrate of iron," purporting to be similar to that of Beral, was offered on sale, in England, by Mr. Bullock.

Early in the spring of 1842, at which time I was superintendent of the laboratory of Messrs. Savory and Moore, I perfected an ammonio-citrate of iron, the existence of which was made known by advertisement. I shortly afterwards completed a series of chalybeate salts, which the respectable firm I served recognized as interesting, and specimens were sent to the museum of the Pharmaceutical Society: this donation was acknowledged in the October Number of the journal in which the transactions of that Society are published. These were the salts sent:—

Citrate of iron.

Ammonio-citrate of iron.

Sodio-citrate of iron.

Magnesian-citrate of iron.

Citrate of iron and quina.

Citrate of the magnetic oxide of iron.

* I cannot suffer this conduct of Monsieur Beral's to pass without marking my disapprobation. It is a pity that men whose names are honourable in pharmacy should so far lend themselves to a selfish and mercenary spirit, as to conceal the nature of a remedy intended for public use, and to adopt a phraseology professedly scientific, but which is inconsistent with the admitted rules of nomenclature.

Ammonia-tartrate of iron.

Potassio-tartrate of iron, *P.L.*

Tartrate of the magnetic oxide of iron.

In making this statement I am anxious not to be misunderstood; I am particularly anxious so to express myself that I may not appear to claim as the result of my own observation what justly belongs to others; I do not contend for priority of discovery in more than one case, *i. e.* the citrate of iron and quina, although, as will be seen, I arrived at the completion of others in an independent manner: the *amber-coloured* citrate of iron and quina, the salt now in use, most certainly originated with myself, and was deposited in the museum of the above-named society long before any other manufacturer had perfected the combination. I frankly acknowledge that my notice had not been directed towards the citrates of iron until Mr. Bullock's preparation (*ferri citras*) appeared; I had never experimented at all on the action of citric acid on the *sesquioxide* of iron before that period, but I had devoted much time to the action of tartaric acid on the same oxide, in consequence of the uncertain results I met with in making the potassio-tartrate *P.L.*, and this circumstance rendered the transition from one class to the other comparatively easy. At the time I produced the ammonio-citrate before alluded to, I was totally ignorant of the compound nature of the salt used on the continent, and brought into notice in England by Mr. Bullock, and it was some time afterwards that I learned that it was other than it pretended to be. My own experience assured me that the *true* citrate of iron was insoluble, or nearly so, in cold water, and this induced me to examine Monsieur Beral's and Mr. Bullock's "citrate." The first experiment was conclusive; a little hydrate of potash was added to a strong solution of the suspected article, heat was applied, and immediately there was a plentiful evolution of ammonia: this result was communicated, and I then asserted (as was afterwards done more publicly), that the term citrate of iron, when applied to a salt which was neutral and soluble, was a misnomer and deceptive; that it misled the physician in an important manner; and the adoption of names was urged "which would indicate the composition of the bodies to which they are at-

tached." I believe this was the first time that the propriety of Monsieur Beral's name had been called in question, and it is a satisfaction to me to find that the erroneous nomenclature is being gradually abandoned. I am fully aware that Mr. Bullock has resisted this statement, but there is surely much that is contradictory in the opposition he offered; and I do think that even to himself it must appear inconsistent: by way of example, he applies the term—

Citrate of Iron and Potash, to a salt consisting of Citric Acid, Iron, and Potash.

Citrate of Iron and Soda, to a salt in which soda is the third constituent.

Citrate of Iron and Magnesia, to one in which magnesia is present.

But when ammonia stands in a similar relation to the acid and iron, it is not, according to the same authority, to be called citrate of iron and ammonia, but citrate of iron, and the simple salt with which it is likely to be confounded goes anonymous. Mr. Bullock has also identified his preparation with that sold by the French pharmacentists, whose language is, "the true name of Monsieur Beral's salt ought to be ammonio-citrate of iron; this point is incontestible." He has stated, moreover, that without ammonia his own salt would be difficult of solution. With what grace, then, do we find him subscribing to the assertion, that the ammonio-citrate of iron is an untried preparation in practice? I do hope that Mr. Bullock will reconsider his observations, that he will retract what he may have said in haste, that he will use his talents in clearing away the difficulties and embarrassments which surround this most interesting question, and be found among those whose high ambition is, to gain a reputation by a straightforward and manly endeavour.

Three oxides of iron require to be mentioned as capable of forming salts with the organic acids—the protoxide, the sesquioxide, and what is commonly called the magnetic oxide. The last named cannot, according to Turner, "be regarded as a definite compound of iron and oxygen, but is composed of two real oxides. It frequently occurs crystallized in the form of a regular octo-

* See Pharmaceutical Journal, Vol. I. p. 653.

hedron and dodecahedron, and it is not only attracted by the magnet, but is in itself sometimes magnetic." It has been of late years artificially prepared by precipitating the two oxides from their solution in sulphuric acid, by means of carbonate of soda, and afterwards boiling the precipitate to drive off the carbonic acid. I purpose, at this time, confining myself exclusively to the combinations of the sesquioxide, reserving the two others till some future opportunity: let me observe, however, in passing, that they are capable of forming double salts of less beauty, though possibly of more value, than those I shall now consider.

The acids I have experimented on are the citric, tartaric, and acetic.

The MEDICAL GAZETTE for 1843, Vol. xxxii. p. 836, contains a speculation somewhat ingenious, by Mr. Mowbray, the author supposing that in some cases where citric acid is employed the elements of the acid rearrange themselves, and form aconitic acid: the whole is purely hypothetical.

Other persons have conjectured that a saccharine principle is occasionally generated.

Then, again, it has been asked, is ferric acid an ultimate ingredient in the double salts of iron? This is a more difficult problem to solve: for a long time I entertained this opinion, but latterly nothing has occurred with me which strengthens the assumption; I shall therefore dismiss these hypotheses, not because I have the impression that ferric acid, a saccharine principle, or aconitic acid, cannot under some circumstances be produced, but because I believe there are instances in which none of these supposed changes take place.

I intend to regard them as composed ultimately of the acids and bases respectively employed in their preparation: 80 and not 40 will be reckoned as the equivalent of sesquioxide of iron: in other respects the proportionals adopted by Mr. Phillips in his translation of the Pharmacopœia will be followed here.

There is peculiarity in the behaviour of the different acids, which forbids my remarking on them collectively.

I shall commence with the action of citric acid on the hydrated sesquioxide of iron.

[To be continued.]

FUNCTION OF THE SPLEEN.

To the Editor of the Medical Gazette.

SIR,

THERE are three vascular systems—an hepatic, a pulmonary, and a general. Each system consists simply of an afferent vessel, and a set of efferent vessels, with intermediate capillaries. 1. The hepatic afferent vessel is the portal vein and ramifications, and its commencement is the spleen. 2. The pulmonary afferent vessel is the pulmonary artery and ramifications, and its commencement is the right half of the heart. 3. The general afferent vessel is the aorta and ramifications, and its commencement is the left half of the heart. 1. The hepatic efferent vessels are the hepatic veins. 2. The pulmonary efferent vessels are the pulmonary veins. 3. The general efferent vessels are the gastric, duodenal, and mesenteric veins, and the superior and inferior cavæ, and the coronary vein.

Now, according to Harvey's doctrine, the heart is the only organ concerned in the circulation; and the right ventricle propels the blood through the lungs, and the left through the rest of the body: in other words, one half of the heart propels the blood through *one* of the three vascular systems—the pulmonary, and the other half through *both* the other two systems—the general, and the hepatic.

Now, as we have implicitly believed this for the last two centuries or so, and during that period have been unable to understand the use of the commencement of the hepatic afferent vessel, is it not about time that we began to doubt a little as to whether the commencement of the *general* afferent vessel is really so obliging as to propel the blood through the *hepatic* system? Would it not be well carefully to examine the whole of the hepatic afferent vessel (spleen, splenic vein, portal trunk and branches), and see whether it is not *itself* adapted for propelling the blood through the hepatic system? And whether its commencement is not for the purpose of communicating motion to the blood, by contracting, and consequently generating propulsive force, as well as the commencement of the pulmonary and general afferent vessels? And whether, as the hepatic afferent vessel differs so materially from

the pulmonary and general afferent vessels, the motion of the blood through the hepatic system is not therefore, and in consequence of that difference, *intermittent and slow*, instead of being constant and rapid, like the motion of the blood through the pulmonary and general systems? And whether the true reason that the commencement of the hepatic afferent vessel is twice as large, relatively to the liver, in man as in quadrupeds, is not because the blood has to be propelled through that organ vertically in the former, and horizontally in the latter? And whether the use of the splenic artery is not simply to be split up into capillaries, for the commencement of the hepatic afferent vessel to originate from? And whether the remarkable tortuosity of that artery is not for the purpose of preventing any considerable or undue quantity of arterial blood from running hot-foot on a foolish errand (pardon the simile!) into the hepatic afferent vessel? With several other *whethers*, "*quæ nunc perscribere longum est.*"

Is it not about time, too, that we gave over fancying that those organs *make* blood, which receive blood, and nothing else, ready made? or of altering blood, or "effecting a peculiar change upon it," when it is plain they neither can add anything to it, nor eliminate anything from it? And, lastly, may we not reasonably begin to suspect that every organ, into which nothing besides blood goes, and out of which nothing besides blood comes, is, as well as the heart itself, subservient, in some way or other, to the circulation or motion of the blood?—I am, sir,

Your obedient servant,

J. J.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

THE PROTECTION AND TREATMENT OF THE INSANE.

— only the public, but even the mass
our profession, are but slenderly

acquainted with the vast gap which still exists in the protection and treatment of insanity: they do not know what crowds of lunatics are not treated at all, what crowds are treated injudiciously! Our readers will have learned from our late article on the neglect of the insane poor in Scotland*, that in three counties alone 200 lunatics are wandering at large.

In England, matters are somewhat better than this, but still very bad; *how* bad, may be seen from a sensible pamphlet written in 1843 by Dr. de Vitre of Lancaster. Last year only fifteen counties possessed asylums, but we believe that the Devonshire one is now completed, making the number up to sixteen. Of these, several are full to overflowing, among which we may cite the one at Hanwell; indeed, in Middlesex several hundred pauper lunatics are in workhouses, or in other asylums, or boarded out. Here is an enormous gap to be filled up.

Criminal lunatics, again, form a class of patients very troublesome in a county asylum, as they require more than usual vigilance on the part of the superintendent. The number of these wretched beings, however, is so small, that we do not think with Dr. de Vitre that it can be necessary to build asylums for their exclusive use. Bethlem (with an additional gallery or two, if necessary) might easily accommodate the seventy one patients of this formidable class now confined in our public institutions, besides the individual cases which may still linger in jails or private asylums.

The Poor-Law Commissioners, in a letter of instructions to Boards of Guardians, which they issued a couple of years ago, observed, that "the detention of any curable lunatic in a workhouse is highly objectionable, on the

* MEDICAL GAZETTE, Feb. 9, 1844.

score both of humanity and economy." And they add, that even the confinement of incurable and harmless idiots in a workhouse is often attended with serious inconveniences.

Yet even in the county of Lancaster, with its large asylum, a great number of lunatics are retained in Union workhouses; for the county institution is filled to overflowing, and contains 616 patients, though built for 600 only.

During the period that the Union house at Liverpool was at the height of its mismanagement, in 1842, this part of its affairs was of a piece with the rest: "in the return for Liverpool, made in July last, it was asserted that all their lunatics were in the county asylum, and that they had none in their workhouse, nor boarded out; whilst, in the investigation into the management of their poor-house in the beginning of the present year [1843], it appeared not only that there were persons of unsound mind in that ill-conducted establishment, but that there were wards peculiarly appropriated to the insane; and that Mr. Clements, the Assistant Poor-Law Commissioner, after minutely inspecting the whole of the poor-house, had promised *that all the lunatics* should be removed from the house. And, in accordance with this promise, 'some of them had gone to Lancaster, and others to the *Liverpool Asylum, where they ought to have gone long before.*'"

Nor are the lunatics in other divisions of the same county disposed of in the best manner. Thus of fifty-three lunatics belonging to the Blackburn Union, only nine are in the County Asylum, the remainder being in the workhouse.

Again, in the Bolton Union, out of fifty-six lunatics only nineteen are in the County Asylum; twenty-nine are in the workhouse, and eight reside with their friends at a weekly allowance.

"Now this workhouse has no wards specially set apart for persons of unsound mind, is only under ordinary circumstances visited by the medical officer three times a week, and it is this very house where a poor woman was recently removed to the dead-house *previous* to death, by a drunken nurse who was employed at five shillings a week to attend the sick. On an inquiry being instituted, it was found that this establishment was so overcrowded, that in one bed-room, containing four beds, no less than sixteen persons were huddled together to sleep."

There is, however, a numerous class of lunatics whose condition seems to be even worse than the state of those who are immured in a union workhouse; we mean those unfortunate patients who are kept in cottages for two or three shillings a week—a payment which includes board, lodging, and clothing!

In such cases, the persons to whom the lunatic is committed have no means of securing him, but the most cruel coercion, and the patient runs the risk of becoming an idiot, or a beast, through sheer neglect. Dr. de Vitré gives some instances of this kind. In one, a pauper, who had been of weak intellect from his infancy, was confined by his parents in a cupboard beneath the staircase of a country cottage. His body had become compressed and contracted by this terrible confinement, and at the age of twenty-eight, when he was removed to the County Asylum, his trunk was bent upon his thighs, and these again upon his legs, so that the knees were under his arm-pits, and literally served him as crutches to rest upon! Sometimes he rested on the sacrum, which was covered with indurated skin. From disuse of the eyes, he was blind, or nearly so, the eyelids being habitually closed. Occasionally, however, he would sit facing

the sun, and open his eyelids, when a small cornea was perceptible. He died after a few years' residence at the Asylum, without any improvement.

In another instance, a woman had been fastened to a bedstead for nearly thirty years. When brought to the asylum, she had entirely lost the use of her limbs, and could not even balance herself on her feet. By removing all fetters, and with a proper course of treatment, she recovered; but, as she did not belong to the county, she was removed by the overseers, *on account of the expense*, as soon as they were convinced that she was not dangerous.

There is a class of cases precisely similar, where the lunatic has a small income of his own, and is taken care of by some near relation. He is at first treated with kindness; but as time wears on, and the patient becomes more troublesome, he is chained in a cellar, abandoned to the care of a servant, and rarely visited by his natural protector. When his funds are exhausted, such a patient is often sent to an asylum as a pauper, and then the whole history comes out.

A patient of this class, near Lancaster, after his money was spent, was regularly farmed out by the parish to the lowest bidder!

A cottager in Gloucestershire, when he left home, used to screw up his wife in a packing-case, with a small hole cut in the lid. She was ultimately set free by the interference of two medical practitioners, was removed to a public asylum, and cured there.

There is again another class of cases, where the family is not indigent, but where, from sheer stupidity, or inveterate ignorance, the patient's interests are wholly neglected. The son of a yeoman in a southern county had an attack of mania. The father, who refused to send him to an asylum, first

chained his son, and afterwards thrust him into a dark hay-loft, where he remained for years. It would seem that a case of this kind is an exception to Blackstone's axiom, that for every wrong there is a remedy. The Secretary of State and the Lord Chancellor were both applied to; but the former could not interfere because the lunatic was harmless, and the latter because he had no property. At last the father died; and the son being then possessed of property, a commission of lunacy was issued to take care of it. He was now quite blind, the cornea of both eyes having ulcerated during his confinement.

In many instances, the maniac wanders as he pleases, like the two hundred lunatics who roam through the counties of Dumfries and Wigton, and the stewartry of Kircudbright. In some of these cases the patient is thought to be only whimsical or eccentric; yet, should he commit a murder, a host of relations and acquaintances rush into the criminal court, and swear that their unfortunate friend has long been as mad as a March hare. And thus our Macnaughtens escape condign punishment, while the wise shrug up their shoulders, and wonder at, without admiring, the refinement of forensic medicine!

It must be confessed that mundane government would be much easier than it is, if the difficulties of legislation were only on one side of a question; unfortunately, they are almost always on both, and to trim the balance, requires a Solon. Thus it would be extremely difficult to authorise by law the interference of strangers in cases where the lunatic roams at large, and his relations do not think it necessary to confine him. As a general rule, such interference would go against the grain, and would be called intermeddling. "If we shut up all the women who

change their minds every minute," asks a physician in a popular novel, "who is to make our shirts and puddings?" "And if we shut up all the men," the public would cry, "who have something odd about them, who is to make our hats and shoes?"

This difficulty, however, will not apply to cases where the lunatic commits acts of violence, as the public feeling would then be with the person interfering. Still less would there be any difficulty in those cases where the unfortunate patient is chained by his relations in a cellar or a loft, and treated like a wild beast—for here the honest indignation of all mankind would glow on the side of the liberator of the oppressed. If, therefore, Dr. de Vitre is right in his law (*sed quare*, as the lawyers say), if there is no redress for such a case as that of the yeoman's son above narrated, the sooner the law is altered the better.

We would also recommend that the inspection of the Commissioners should be extended to those cases where a single lunatic is confined by himself. Even a lunatic in good circumstances is not always treated with decency. In a remarkable instance of this kind on which the Lord Chancellor of Ireland commented in January 1843 (*in re Spread*), the lunatic was found stark naked, in an out-house, with his legs clenched and chained together, and fastened by a chain only two feet long, without straw, and unable to lie down so as to rest himself.

COLLEGE OF PHYSICIANS.

A MEETING of the Fellows of the College of Physicians was held on Wednesday, for the purpose of choosing a successor to Sir Henry Hallford. It was generally understood that Dr. Paris was to be the new President, and accordingly at the close of the ballot it was found that he had been duly elected.

SIR JAMES GRAHAM'S MEDICAL REFORM BILL.

A FEW evenings ago, on a question being put to Sir James Graham on the above subject, he replied "that he should be prepared before Easter, or immediately after, to introduce a measure generally affecting the medical profession throughout the United Kingdom, not increasing but relaxing the restrictions on the practising of medical men."

We understand that the chief provision of the new bill will be the establishment of a Council of Health and Medical Education for the government of our profession.

It will be composed of one of the Secretaries of State; the Regius Professors of Physic at Oxford, Cambridge, and Dublin, and one of the Edinburgh medical professors; three physicians and three surgeons as representatives of the Royal Colleges of England, Scotland, and Ireland; six other persons (laymen, probably) to be appointed by the Queen; and a representative of the provincial practitioners of England.

The Queen will appoint all the members of the first Council, except those who will sit by virtue of their office.

The three grades of the profession will be preserved.

No one will be licensed to practise as a physician till he has attained the age of 26, nor as a surgeon, till he is 25; but licentiates in medicine and surgery (general practitioners) will be allowed to commence practice at 21.

The new council will entirely overrule the existing medical corporations, who will do little more than register its decrees.

Such, we believe, will be found to constitute the chief points in the new measure; we refrain, however, from all comment till the Bill itself, or an authentic draft, is before us.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

Saturday, March 2, 1844.

THE PRESIDENT IN THE CHAIR.

On the Early Organization of Coagula and Mixed Fibrinous Effusions, under certain conditions of the system. By JOHN DALRYMPLE.

THE object of this paper was to confirm an observation published by the author in the

twenty-third volume of the Transactions of the Society, as to the organization of a clot of extravasated blood in a man dying of scurvy. Some doubt had been thrown upon the presumed nature of this clot, and the character of its vessels, by Mr. Travers, in his recent able and elegant work upon inflammation. A fresh example of a similar coagulum, injected by Mr. Busk, of the Dreadnought Hospital Ship, gave the author an opportunity of more minutely examining its condition, and proving its organization.

In the knee-joint of a Lascar, who died of scurvy, Mr. Busk found several clots of extravasated blood. Some floated loose in the fluid; others were attached to the synovial membrane of the capsule of the joint. The attached clots were minutely injected; but, independent of the vascularization, the fibrinous materials of the blood (the white corpuscles) were found in various stages of development into tissue. There were normal white corpuscles; simple nucleated cells, the cells becoming elongated and caudate; others more elongated, and often bifid; and at last the elongation into filament, as the final conversion into tissue. All the cells were nucleated, and had nucleoli. Interspersed among the cells and filaments were innumerable perfect blood-discs, which gave the clot a dark-red or nearly black colour.

The loose coagula were of course non-vascular; yet the fibrinous corpuscles had commenced a process of organization, and were converted into elongated and nucleated cells; these were equally interspersed with normal blood-discs, and equally darkly coloured.

After some remarks upon the cachectic condition of the subjects of these extravasations, the author concludes by stating, that it is not now, nor ever was, by him, contended that ordinary extravasations of blood in the healthy body become organised, but rather that the tendency is towards degradation, disintegration, and absorption, than advanced development in the blood so effused.

On the Composition of the Meconium, and of the Vernix Caseosa, or Lubricating Matter of the New-born Infant. By JOHN DAVY, M.D. F.R.S.L. & E.

The microscopical character of meconium is very distinctive, and well displays its compound character; it exhibits a confused mixture of globules, plates, and molecules. The globules, about 1-3000th of an inch in diameter, are very abundant, and form a principal part of the whole. Judging from their form and size, and their insolubility in water and alcohol, they may be inferred to consist chiefly of mucus. The plates are of

two kinds: one of irregular form, varying in form from about 1-2000th to 1-1000th of an inch in diameter—insoluble in water, hot or cold alcohol, the dilute acids and alkalis—like epithelium scales, which the author believes them to be. The other kind of a regular form, of great thinness and transparent, insoluble in water and acids, and in cold alcohol, but soluble in hot; properties indicative of cholesterine. The molecules vary in size from 1-8000th to 1-20,000th of an inch in diameter; and being insoluble in water, and soluble in alkaline ley, may be considered as consisting chiefly of fatty matter.

Besides these ingredients, to which the meconium owes its thick consistency and viscid nature, there is another portion from which the mass derives its colour and taste, and probably its power of resisting putrefaction, and which seems identical with the sapid and colouring matter of the bile. The specific gravity of meconium exceeds that of water; it sinks in a saturated solution of common salt of the specific gravity 1.148. The quantities of meconium which the author has obtained have been too small to admit of accurate analysis; but in a specimen obtained from a healthy child immediately after birth, the proportion of ingredients was determined, and the results per cent. were about as follow: these proportions, he believes, may be considered pretty correct:—

23.6 mucus and epithelium scales.

7.7 cholesterine and margarine.

3.0 colouring and sapid matter of bile and oleine.

72.7 water.

100.0

A portion of the same meconium was incinerated; it burnt with a bright flame, and left 69 per cent. of reddish ash, chiefly peroxide of iron and magnesia; with a trace of phosphate of lime and common salt.

The *vernix caseosa*, examined under the microscope, is found to be composed of granules, plates, and molecules. The plates constitute the principal part; they have the properties of epithelium scales; the granules, those of fatty matter; as also the molecules. The plates are insoluble both in weak acids and alkaline ley, and in hot and cold alcohol; are of irregular form, varying in size from about 1-666th to 1-1000th of an inch in diameter. The vernix is apparently lighter than water, on which it floats; but this is owing to the air entangled in it. If subjected to the action of the air-pump immersed in alcohol, it sinks in water at 60° Fah.; a specimen thus treated was of the specific gravity 1.0039. Of a butyaceous consistence in its ordinary state, at a tem-

perature of 60°, it hardens on reduction of temperature, and becomes almost semi-fluid when its temperature is raised, as to 100°—admirably adapting it for a lubricating substance in parturition.

A single specimen of the lubricating matter, of great purity, was subjected to analysis, and found to consist of—

13·25 epithelium scales.

5·75 oleine.

3·13 margarine.

77·87 water.

100·00

The author remarks that, theoretically considered as regards the origin of the two substances, the preceding results seem to point out distinctly that both are excretions; the meconium chiefly derived from the liver, and the lubricating matter from the skin. He alludes to the opinion of M. Raspail, that a portion of the meconium consists of intestinal villi, but says he has in vain sought for the appearances which M. Raspail describes.

Vauquelin and Buniva, from examination of the lubricating matter, were led to infer that it is not an excretion from the infant, but a deposit on its surface from the liquor amnii. This opinion, the author remarks, does not require to be controverted. Bichat rejected it, from the circumstance that no such deposit is found on the umbilical cord, and on the inner surface of the amnios; and came to the conclusion which seems most just, that it is derived from the skin of the fœtus, and is a secretion similar to that which takes place after birth from many parts of the cutaneous system.

Account of a Specimen of Partial Fracture of the Neck of the Thigh-bone; and of the proper Source of Nutrition of the Head of the Bone. By T. WILKINSON KING, Esq. [Communicated by B. B. COOPER, Esq., F.R.S., &c.]

The specimen described by the author, and which was exhibited to the Society, was obtained from a patient 72 years of age, who died of pneumonia, fifty-four days after having received an injury to his hip. The neck of the femur was nearly divided by fracture at its narrowest part; all that retained the fragments in union being one-third of the shell, at its upper and anterior part. The head was deflected backwards, and the buttress of the neck was driven into the cancelli about a third of an inch. The soft tissues were healthy. The only trace of new ossification was at a point on the base of the buttress. The author then referred to other cases on record, of a similar partial fracture of the cervix femoris.

He afterwards proceeded to detail some

observations which he had recently made of the arteries which supply the head of the thigh bone. He has found that the artery which goes to this part while it is an epiphysis, is persistent through life: it is a large terminal branch of the internal circumflex artery, which enters a foramen a little behind and below the highest point of the neck of the femur; after this, it curves over the denser layer of cancelli left by the union of the epiphysis to the shaft, directing its course beyond the insertion of the round ligament, to which, he thinks, it furnishes nourishment. He concluded by making remarks on the influence which this vessel may possess, in cases of fracture of the neck of the femur, in preserving the vital actions of the head of the bone, and assisting the process of union by ligament; as in examining specimens of that kind, he has observed that it takes a course when it is not liable to be torn by the injury which produces the fracture. In a note appended to his paper, the author mentions that he has found a vessel supplying the head of the humerus, which pursues an analogous course to what which goes to the head of the femur; that is, it passes specially, by a foramen in the cervix, to the part which was originally an epiphysis. The paper was illustrated by drawings.

The Influence of Weather on Disease. By JOHN WEBSTER, M.D. F.R.S. &c.

Even so early as the days of Hippocrates, the influence of weather in the production of disease was the subject of observation. Since then, physicians, both ancient and modern, have occasionally alluded to some of the points discussed in the present communication. With the view of bringing these interesting questions under the notice of the Society, the author stated various facts respecting the prevalence of particular diseases at different seasons, which he had collected whilst one of the physicians of the St. George's and St. James's Dispensary; where regular reports of the weather, and its changes, with a register of the prevailing diseases were kept by Dr. Gregory, and himself, during a series of twelve consecutive years. Numerous tables illustrative of the maladies met with during the year are given, from which it appears that affections of the chest were more common during cold than mild weather; whilst fevers and abdominal complaints came much oftener under observation in spring and summer than at other seasons.

According to a return of all the medical patients admitted, April was the most unhealthy month of the year, December being the most salubrious. Respecting the general character of disease, those of the chest were comparatively the largest in proportion, con-

stituting upwards of 27 per cent. of the entire admissions. Affections of the abdominal viscera were next, being 26 per cent. of the whole. Then fevers, which comprised 15.50 per cent.; other forms of disease being likewise enumerated. From these tables it appears, that chest affections were most numerous in January, and least so in September; whilst complaints of the abdominal viscera were most common in August; but April exhibited the largest number of fever cases, December and March the fewest.

Some details are next given respecting pneumonia and pleurisy, shewing that the cold weather of January was most inimical to patients predisposed to these affections, of which very few cases were met with during the warm weather of August. The remarkable infrequency of inflammatory diseases of the organs of the chest, subsequent to the appearance of the cholera in London during the year 1832, is afterwards adverted to by the author, since which time similar affections became not only less numerous at the Dispensary, but the antiphlogistic treatment, hitherto so useful, required to be adopted with the greatest caution.

Few complaints appeared to be more modified by particular kinds of weather than those in which a discharge of blood took place from an internal surface; hæmoptysis being the disease of that description most frequently met with; of which fewer cases occurred during the colder months of the year, than in the warmer weather of spring, and the beginning of summer, as shewn by the fact, that out of 107 patients attacked with spitting of blood, only five took place in all the twelve Januaries referred to, whilst seventeen cases occurred in the April months.

The author afterwards alludes to the influence which particular seasons exert upon febrile diseases, eruptive complaints, affections of the head and nervous system, as also upon local diseases. Subsequently a table is given of the proportion of the patients cured and died during the different months of the twelve years included in his paper; according to which return more patients were discharged cured during the months of November and September than at any other period of the year; December and January shewing the fewest; whilst the proportion of deaths was greatest in February, but smallest in April. Diseases affecting the abdominal viscera were most fatal in September, fevers in August; affections of head and nervous system in October and May; whereas eruptive complaints exhibited the great mortality in September.

After some observations respecting the difficulty of drawing correct conclusions respecting the influence of weather on disease,

the author states, among other opinions, that menorrhagia occurred oftenest with south-westerly winds, and especially after thunder; whilst rainy and windy, or stormy weather, with a falling barometer, occasioned hæmoptysis; whereas clear, frosty, and dry weather, accompanied with northerly winds, favoured the appearance of scarlatina. Other illustrations are also given, drawn from a careful examination of the registers kept at the Dispensary, and from the author's personal observation, which he hopes will be viewed simply as an attempt to elucidate a very intricate question, and one hitherto but partially investigated.

Mental diseases, like those affecting the body, appear to be influenced also by the varieties of season; to illustrate which proposition, the author gives an elaborate table of the total number of male and female lunatics admitted into Bethlem Hospital during the different months of the last twenty-one years. According to that statement, insanity was more prevalent during the warm weather of summer, than in the mild or cold season; more female patients having been received in May, and males in July, than in any other month of the year; the mortality being just the reverse; that is, more deaths took place in January, than at any other period, and the fewest in the warm weather of June, when only 3.28 per cent. of deaths are reported; whereas in the January months the proportion of fatal cases was 10.91 for every 100 patients admitted.

The ratio of cures was also considerably influenced by the season of the year, since more patients were discharged convalescent in the autumn, and when the weather became temperate, than either in the spring or summer; for example, during the months of May, the per centage of patients discharged cured was only 37.47; whilst in the Novembers it rose to 67.23 per cent.

After making some general remarks upon the different points embraced in his paper, the author concludes with expressing a confident hope, were the subjects now adverted to investigated in the manner their importance deserves, much useful information would be obtained; particularly if the inquiries were carried on under the superintendence of the medical officers of public institutions, where similar investigations can be best pursued, so as to arrive at satisfactory as well as instructive conclusions.

DANGEROUS MISTAKE IN THE FRENCH CODEX.

In our number for October 30th, 1840, page 222, we gave the receipts for two pur-

gative emulsions taken from the French Pharmacopœia. One is made with twelve grains of jalap, and flavoured with two drachms of orange-flower water; the other is made with twelve grains of scammony, and flavoured with *two drachms of cherry-laurel water*. This would probably be a fatal dose, and we therefore spoke too cautiously, when we said, "on account of the depressing effects of this remedy, we apprehend it would be better, in many cases, to substitute orange-flower water as in the previous formula."

This dangerous mistake exists both in the original Paris edition of the codex, and in the Brussels reprint.

Soubiran gives a similar formula, which he calls *Potion purgative de Planche*, but it contains only six grains of scammony, and is flavoured with only *four drops of cherry-laurel water*.—*Nouveau traité de Pharmacie, par E. Soubiran, seconde édition, tom. i. p. 664.*

FREDERICK THE GREAT'S ANTI-PHLOGISTIC REGIMEN.

ZIMMERMAN, in his narratives of his interviews with Frederick the Great, of Prussia, says, "To-day the King had taken a great quantity of soup made as usual of the strongest gravy drawn from the most healing things. With his portion he mixed a large table-spoonful of pounded mace and pounded ginger. He then eat a large slice of beef stewed in brandy. This he followed up by a copious allowance of an Italian dish, composed half of maize-flower and half of parmesan cheese; to this is added the juice of garlic, and the whole is fried in butter till it acquires a crust as thick as one's finger. This favourite dish is called *polenta*. At length, (continues Zimmerman), the King, praising the excellent appetite which the dandelion had given him, concluded the scene with a large plate of eel-pie, so hot and so highly seasoned that it seemed to have been baked in hell; while at table the King fell asleep, and was seized with convulsions.

FOTHERGILLIAN MEDAL.

THE Fothergillian gold medal was presented to Mr. Roberts (not *Roberts*, as stated by mistake last week), of Great Coram Street, for an essay on scarlet fever.

ON

DIFFERENT FORMS OF GRANULAR
DISEASE OF THE KIDNEY.

By J. D. HEATON, M.D.

[Concluded from p. 715.]

(For the *London Medical Gazette*.)

IN addition to the five cases already detailed, two others occurred during the three months of the summer session of 1841, which were both suspected to be the same disease, though no opportunity of verifying this supposition was afforded by a post-mortem examination.

The first of these was a man 65 years of age, admitted under Dr. Williams on the 8th of June, a tailor, of emaciated appearance; habits temperate. He came into the hospital suffering from a variety of disorders. The report states that he has long been affected with various dyspeptic symptoms; and for a considerable time has had a troublesome cough, with occasional expectoration of blood. The physical examination of the chest gives distinct evidence of a cavity towards the apex of each lung. Besides these complaints his legs have been very oedematous since last Christmas, though he has, for many weeks, been passing an unusual quantity of pale limpid urine. The urine which he passes at present has a specific gravity only of 1006; it is very pale and clear, but contains no albumen.

This patient remained in the hospital about three weeks. He was treated for his dyspeptic sufferings, and also to relieve his cough; but as he did not seem to be a very fit subject for in-door treatment, he was discharged at the end of this period, without deriving any very decided benefit.

This is a rather obscure case; but though it is impossible to speak with certainty, yet it appears not improbable that, in addition to chronic phthisis and dyspepsia, there was

also a granular degeneration of the kidneys. The only symptom directly referrible to these organs was the morbid state of the urine, which presented, however, little more than the characters of a simple hydruria. During the time that he remained in the hospital it contained no albumen: still, though the presence of albumen is a usual, it is far from being an invariable or essential symptom of a granular state of the kidneys; it is very frequently absent during the advanced stage of the disease in a chronic form, when the urine may merely present the characters described in the present instance. It is important, however, to observe, that a considerable anasarca coexisted with this inordinate discharge of fluid through the kidneys. Christison has had very extensive opportunities of observing the disease in question, and he gives it as his opinion that, except in the case of diabetes mellitus, dropsy never coexists with a continued discharge of urine in quantity considerably above the natural amount, except in cases of granular disease of the kidneys. Believing this opinion to be correct, it is on this circumstance more particularly that I found the opinion that this disease existed in the present instance.

The dyspeptic symptoms, from which he had long suffered, are very intelligible on this supposition, as chronic dyspepsia, in various forms, is a very frequent concomitant of this disease.

The only point of interest in this case is the continued absence of albumen from the urine of a person supposed to suffer from the peculiar degeneration of the kidneys at present under consideration; and the grounds for this diagnosis, viz. the continued discharge of an unnaturally large quantity of urine below the healthy specific gravity, in connection with a dropsical state of the cellular tissue.

The other case to which I have to refer presents the early history of a less doubtful

example of this disease, but which is unfortunately deficient of its termination.

Henry Yemm, admitted under Dr. Williams, July 23, 1841; a cabinet-maker, of rather short stature and stout make. He has always enjoyed good health till about three weeks before admission, when he got wet through, and remained some time in his wet clothes. Two days after this his face began to swell, and subsequently oedema of the legs, and ascites, made their appearance.

When admitted, the subcutaneous cellular tissue was almost universally oedematous, and there was distinct fluctuation of the abdomen. The urine was clear, but pale and rather scanty; it had a specific gravity of 1012, and was strongly albuminous. He had a dull aching in the loins, but was free from pain with this exception. The pulse regular, but of natural frequency, and small and wiry.

The treatment consisted in cupping over the loins, purgative doses of cream of tartar, and a diuretic mixture containing tincture of cantharides. The patient remained in the hospital three weeks, and was then discharged at his own request. At this time the dropsy was almost removed, and he felt better in his general health. The urine had acquired a specific gravity of 1020, but still contained albumen.

About a week after his departure the dropsy again returned; his health and strength fell off, and he suffered from much sickness. On the 7th of September he again applied for admission. The symptoms were much sickness, shortness of breath, some cough, and a general state of dropsy. The face, besides being bloated, was pale and anæmic. The urine was pale, of low specific gravity, and albuminous. He was again treated by cupping over the loins, hydragogues, and diuretics. He afterwards took creosote in doses of ℥ij., and used warm baths. Early in October he had much pain and tenderness in the abdomen, which was much distended with fluid: this was relieved by the application of leeches.

Very little relief was afforded on this occasion by any plan of treatment; the dropsy could not be removed, and the dyspnoea continued, with occasional sickness. The urine was generally of about natural quantity, but contained albumen, and was of a low specific gravity. He was discharged on the 3d of November, at his own request, the symptoms continuing very similar to those at the time of his admission.

The seven cases of albuminuria which have now been related occurred during the three months of May, June, and July, in the year 1841. The number is considerably above the average proportion of cases of this disease usually occurring in the medical

wards of the hospital. It is uncertain whether this can be considered a mere accidental coincidence, or as depending on some atmospheric peculiarity, or other general circumstance. If the latter, a corresponding increase might likewise be expected in other hospitals in the metropolis during the same time. I am not aware whether this was the case. It is quite certain that in many of these instances the disease had existed in a less active state for a long period previously to their being admitted into the hospital; but this does not interfere with the possibility of some atmospheric influence, or other cause, exciting at this time a previously passive disease into fatal activity. Dr. Prout has particularly noticed the effects of malarious influence in altering the characters of the urine; and the same cause which would disorder the functions of a healthy organ may well be supposed capable of still further perverting those of one which is diseased. A cold moist atmosphere is fully recognised as having an injurious influence both in exciting and aggravating the symptoms of the granular degeneration of the kidneys; such, however, was not the character of the weather at this time, being generally fine and mild, and during the summer season. If any atmospheric influence operated in reference to these diseases, it must therefore have been of a more obscure, less cognizable character, than those peculiarities which constitute the states of the weather appreciable to our ordinary sensations.

Perhaps these cases, taken in connection, may be considered as affording some illustration to the views which Dr. Williams has for some years explained in the wards of University College Hospital, and has now embodied in his late work on the Principles of Medicine, as to the analogy which exists between various organic diseases affecting certain viscera, but not of a malignant nature. Tubercle in the lungs, cirrhosis of the liver, granular degeneration of the kidney, and opacity and thickening of the valves and membranes of the heart, are all regarded as the result of a deposit of lymph of a caco-plastic or imperfectly organizable character; such lymph shewing a strong tendency to induration and contraction subsequently to its deposition, the more marked as it is the further removed from the healthy standard.

Lymph of this imperfect nature may be deposited as the result simply of local causes, as we see in the contracted cicatrices resulting from extensive burns, and other serious injuries of the surface; but, as affecting internal organs, it usually depends on some imperfection of the system or constitution, analogous to that seen in persons of a scrofulous habit, and which may be either congenital, or developed in the individual *de*

novo. In such individuals it may be deposited in an organ either in consequence of inflammation, acute, or more usually of a low and chronic character; or, where the constitutional predisposition is strong, instead of the healthy lymph supplied for the ordinary textural nutrition of all parts, without any previous disease in the affected organ.

Resulting, then, from the same unhealthy state of the constitution, and differing in their symptoms and physical characters rather from the circumstances of the organ affected than in their essential nature, a very probable opinion might be formed, *à priori*, that the diseases already mentioned—and if there are others of an analogous nature—would be found, in many instances, more than one of them affecting the same individual. Almost each of the cases already related confirms the truth of this opinion. We have seen the granular disease of the kidney connected with tubercle of the lungs, and with a cirrhotic state of the liver, one or both, in many instances; also, with diseased valves of the heart, and with tubercular deposit on the peritoneum. It is perhaps questionable how far softening of the brain, in any of its forms, can be included under the same category as the diseases already mentioned; it is, like them, an organic change, wanting the true characters of a malignant disease, but it presents none of the tendency to contract which, at one period or another, is common to the other diseases enumerated. This may, perhaps, merely depend on the great difference which exists between nervous matter and all the other textures of the body; the fatty matter of the blood, rather than the liquor sanguinis, being perhaps more particularly poured out for the nutrition of this tissue. Certainly softening of the brain is, like them, dependent on a degeneration of the healthy tissue, and probably of a constitutional origin. In two of the cases this disease coexisted with the degeneration of the kidney, which led to their introduction here.

As to the case of tubercle of the lungs, so with regard to the disease of the kidneys under consideration, it has been a matter of considerable discussion whether it be of an inflammatory nature or otherwise. That view which, with regard to the former disease, served both to explain the cause of the question, and to afford its solution, serves the same purpose with regard to the latter, namely, that being a disease which, from its nature, may depend either on constitutional causes merely, or on this as a predisposing cause, but excited by a local inflammatory action: both opinions seem to be true in different instances, and in support of both many cases may be brought forward. In

some of the cases here related probably the disease may have had merely a constitutional origin; for no cause appears likely to produce an inflammatory action of the kidneys, nor can it be ascertained that the symptoms of such a state have at any time existed: the disease has slowly invaded, and only been discovered when so far advanced as to produce dropsy or other easily recognisable symptoms. In other instances, either an exposure to cold, or habits of intoxication—both causes likely to produce congestion or inflammation of internal organs—have preceded any of the symptoms of the disease; in these instances the disease has probably taken its origin in a congestive or inflammatory state of the kidneys. Certainly most cases which develop themselves suddenly as an acute disease may generally be traced to some such exciting cause; and in such cases the antiphlogistic treatment is that which is necessary, and is most successful.

An instance of this presented itself in a man under the care of Dr. Thomson, in the same hospital, but some time before the period when these cases occurred, where the disease was too far advanced to hope for cure, but where cupping over the loins had been tried on various occasions; and it was noticed that for a few days after each application of this remedy the amount of albumen in the urine was occasionally diminished, and the urea augmented. Here, probably, an inflammatory state of the kidneys coexisted with the albuminous degeneration.

The correct view of the nature of the disease seems to be, that it depends on a deposit of lymph of an imperfect character in the texture of the kidney, affecting particularly the cortical substance, but as the disease advances invading also the tubular structure. That where the constitution is very imperfect, this may depend on constitutional causes merely, in which case the bad lymph is deposited in the ordinary process of textural nutrition, but that in many cases this constitutional cause may be aided, and the disease excited, by an inflammatory state of the affected organ, in which case the bad lymph may be poured out not merely in connection with the nutritive process, but as an inflammatory effusion.

Allowing to the kidneys the property which Dr. Prout supposes them to possess, of exerting a disorganizing influence on the materials to be discharged by these organs, it appears sufficiently intelligible why, when the proper texture of the kidney is supplanted by a morbid deposit, these organs should lose this property, and pour out, as through a mere filter, the fluid part of the blood, retaining more or less of its albuminous character. It seems difficult to afford a probable explanation of the great diminu-

tion in the amount of the red globules in the blood, which seems essential to this disease. Whatever this may be, it is not unlikely that the great tendency to dropsical effusion depends on this state of the blood; as in chlorosis,—another disease in which there is a great diminution of the colouring matter of the blood,—there is a very similar tendency.

Little has been said on the subject of treatment; that was not the object with which these cases were reported. In a series of cases, most of which have proved necessarily fatal, and none derived permanent benefit, small opportunity is afforded for conclusions on this subject. I believe it is only in a very early stage that a cure can be accomplished; when at all advanced, though perhaps less rapid in its progress than pulmonary consumption usually proves, it has an equal certain tendency to a fatal result. When there are any symptoms of an inflammatory action, local antiphlogistic treatment will be required, and especially at an early period of the disease. In general I have found no remedy afford so much relief to the uneasy sensations of the patient as rather large purgative doses of cream of tartar, administered two or three times a week. In the cases (I believe not very numerous) where the disease gives a tendency to profuse diarrhoea, this treatment will not be suitable nor required. In addition to this, some diuretic remedy, especially the *infusum diosmæ*, combined with *Spr. Æth. Nit.* and *Tr. Scille*, affords temporary relief.

I am not aware that I have seen any benefit afforded by the *Tr. Cantharidis*; a remedy which has been supposed particularly applicable to these cases. Mild diaphoretic remedies are also beneficial. A careful attention to regimen and diet, and the administration of suitable remedies to remove any unfavourable symptom which may present itself, is a direction necessary in all cases. As to whether any of the preparations of iodine, which have been supposed beneficial in pulmonary consumption, by correcting the constitutional disorder with which that disease is connected, would be similarly beneficial here, I cannot give any decided opinion. The great tendency to anæmia or leucophlegmasia which exists, would seem to suggest the use of chalybeates, though without that expectation of permanent benefit from their use which we have in chlorosis, where there is no serious organic disease. This also is merely a suggestion, on which I cannot yet give the results of experience.

ON THE INJURIES TO HEALTH OCCASIONED BY BREATHING IMPURE AIR IN CLOSE APARTMENTS.

(For the London Medical Gazette.)

NOTWITHSTANDING the various inventions and improvements which distinguish the age we live in, it is lamentable to observe what little attention has been paid to the ventilation of apartments, in which we are destined to pass a greater portion of our lives, and in which a constant and well-regulated supply of the element we breathe is so essential to bodily health and mental enjoyment.

This inattention can only be accounted for either by an apprehension on the part of our architects and builders that the introduction of any thing new would expose them to the charge of a want of taste, or of that acquaintance with the style of the ancients to which it is the fashion so strictly to adhere; imitation being, in their opinions, more deserving of commendation than a desire to meet the improvements of the age; and fashion of more importance than health. If they construct our doors and windows in so superior a manner as to exclude every possible particle of air, they flatter themselves with having attained an advantage to which the inhabitants of ancient Greece and Rome did not aspire. They should, however, recollect that the ancient architects of warmer climates did not overlook the necessity of a free admission of air, and also that a constant supply and free circulation of this element is as necessary for sustaining life as a given quantity for the combustion of the fuel we require to warm our apartments: they nevertheless only provide for the latter, as if the former, although the more important, was of minor consideration, or that they conceived the chimney-draft sufficient for both purposes, when, in reality, it does not answer that for which it is principally intended—as by far the greater portion of the heat generated in our open fire-places is carried up the chimney by sharp currents of air from occasional openings of doors, or such crevices as it may force its way through, being, moreover, frequently productive of serious bodily injuries, while it cannot be sufficient for the purposes of wholesome ventilation: this air being colder than that already in the room is consequently of greater specific gravity, and must form a lower stratum, not unfrequently felt by those placed round the fire suffering from an undue proportion of heat at one side, and of cold at the other.

It should also be borne in mind that the openings of our fire-places being seldom more than three or four feet from the floor,

the upper stratum of air is neither removed or purified by this under current, and must, from being breathed over and over again, be productive of most prejudicial effects, and that this contamination of the atmosphere is considerably augmented at night by the combustion of lights, the quantity of air breathed by an ordinary-sized person being calculated to be about 2000 cubic feet per hour, and that two mould-candles consume as much of the oxygen of this air as a human being, the nitrogen and carbonic acid gas which remain being peculiarly inimical to animal life, and that when carried up by the currents occasioned by combustion and respiration, they must be repeatedly inspired in this upper stratum before they make their escape into the chimney—the only ventilating flue with which our houses are provided; that the heat thus generated is in proportion to the quantity of oxygen abstracted from the atmosphere, which enters into combination with the carburetted hydrogen of the flame of candles, coal, gas, oil, or other inflammable matter from which light is produced; that every cubic foot of carburetted hydrogen consumed unites, on an average, with two cubic feet of oxygen (that portion of the atmosphere required to support animal life); and that the product of this combustion is about two inches and a half of water and one of carbonic acid gas, which, when inhaled in its pure state, proves instantly fatal; and the greater the proportion we inhale in addition to the animal vapours evolved from the lungs and skin, the more pernicious the effect.

Supposing, for example, that the perfect lighting of an ordinary sized apartment requires fifteen cubic feet of carburetted hydrogen per hour, this would form about a pint and a half of water and fifteen cubic feet of carbonic acid gas, which are the products of the combustion, whether the carburetted hydrogen is obtained from wax, tallow, oil, or coal. If, therefore, the lighting continues in an unventilated apartment for seven hours, one gallon of water is produced, the greater part of which must be deposited on the walls, windows, furniture, polished metal, or other cold surfaces with which it comes in contact; and to some articles of this nature it is known to prove highly prejudicial, in addition to the injury to health occasioned by an increased quantity of moisture mixed with the air we breathe. As one of the principal functions performed by this air for the preservation of health is to carry off with it a considerable quantity of vapour, in order to prevent its undue accumulation on the lungs, it is therefore evident that after it has been already so loaded it cannot properly perform these functions, and that consumption and other complaints are thus frequently induced.

The prejudicial effects of carbonic acid gas (which is the same as the choke-damp of mines), as well as of the nitrogen of the air, which is set free by the abstraction of the oxygen (and amounts in quantity to four times that of the oxygen), are well known, and ought, by all possible means, to be provided against. This has been attended to within the last few years in some of our public hospitals, and the mortality in consequence considerably decreased; and likewise in several of our manufactories and public establishments, where the diseases generated by the number of persons congregated in such establishments have been proportionably diminished. In the House of Commons also, where hundreds of members, with hundreds of candles burning at night, tended so much to vitiate the atmosphere, important improvements, in lighting as well as ventilation, have been recently made; but in our domestic establishments little or no attention has been paid to this important subject; and the foundation of a variety of diseases must be the result, particularly from the foul air breathed at balls and other crowded assemblies. The confinement of air in our churches and places of public worship must also be highly prejudicial, as we are frequently exposed, on entering one of these edifices in the summer months, to an atmosphere ten or fifteen degrees below that of the external air, independent of the stagnant state in which it has been allowed to remain during a whole week, often vitiated in a greater degree by the gaseous matter evolved from human remains; and in private houses much inconvenience is thus experienced in close and gloomy weather, an evil which has been considerably augmented by close stoves when made of iron, and heated to a certain temperature. But if stoves were constructed of masonry throughout, as in many other countries, or of fire tiles, or porcelain plates imbedded in mortar, with well-regulated flues, they would be far preferable to open fire places, this substitution of imperfect conductors of heat being not only consistent with the principles of economy in the preservation of heat, and its more uniform distribution through apartments, but more salubrious than the methods usually resorted to in this country, of warming air by contact with iron stoves or pipes.

The healthy appearance of those who pass the greater part of their time in the open air sufficiently indicates its advantages. Armies are also well known to have far greater numbers of sick when well housed, than when exposed in a campaign to the vicissitudes of the season, for weeks and months without any other covering than the canopy of heaven, or occasionally of a tent, hut, or the shade of a tree. These facts ought to satisfy

us that we should admit the air as freely as possible into our apartments, at all seasons of the year, as the temporary and often imaginary inconvenience of a little cold, when compared with the decided disadvantages of breathing impure air, is by far the lesser evil.

When ventilation in large establishments or public buildings can only be obtained by artificial means, it is produced by pumping air in, and drawing it out by a fan worked by steam or other adequate power; and affording it the means of free circulation, either cooled, heated, or in its natural state, through well-regulated apertures in the floors, walls, or ceilings: and in coal mines by flues or shafts, in some of which constant ascending currents of air are maintained by the combustion of fuel, or coal gas, which produces descending currents in others at the same time.

The importance of this subject has been frequently pointed out by scientific men of considerable eminence, without attracting that attention which would have prevented many persons from being imperceptibly hurried to an untimely end. It is therefore to be hoped, that the powerful engine of the press will continue to lend its aid in exposing these evils, until it impresses upon the public mind, and more particularly upon our architects and builders, the urgent necessity of providing against them. Is it not possible by some simple contrivance to make the heat produced in the lighting of apartments, as in the House of Commons, available for their perfect ventilation? If any of these gentlemen succeed in the introduction of this system into private houses, they will be entitled to greater gratitude for this achievement towards the preservation of health and prolongation of life, than any claimed by those heroes whose victories have contributed so much to the miseries of the human race, and the destruction of the human species.

But we ought not, perhaps, to be so much surprised at the slow march of intellect in this respect, when we find so many centuries to have elapsed, before it was so generally admitted as at present, that pure water, another element bountifully supplied by nature, is preferable to any other beverage for insuring the health and happiness of mankind; and when we have so many temperance societies, and other advocates for impressing upon the minds of our fellow-subjects the necessity of becoming converts to the imbibing of this element in its pure state, ought we not with still greater reason to endeavour to make a similar impression, as to the advantages of inhaling with equal purity the lighter fluid, of which we stand so much in need, and which we so much more frequently require?

CONTRIBUTIONS

TO THE

PHYSIOLOGY OF THE HUMAN OVARY.

By CHARLES RITCHIE, M.D. Glasgow.

*(For the Medical Gazette.)**[Continued from p. 797.]*

PART II.

SECTION II. — *Ovaries of women who died within one month after delivery at the full period.*

1. — —, a young woman, who died of peritonitis, &c. a few days after delivery. One ovary was larger than the other, and, on rubbing it between the fingers, a flat circular hardness, of about the size of a dried pea, was perceived, having its outer surface slightly umbilicated by the remains of a small triangular cicatrix. On dividing this tumor it was seen to consist of a contracted circular cyst, the walls of which were of a very faint yellow colour, and of an obscurely radiated or linear structure, bounded on their outer margin by what appeared like a distinct membrane, and, more externally, by an investment of stroma; while, internally, there was an opaque central point, of the size of a pin-head, having a puckered stellated look, as if from the shooting out of various prolongations among the folds of the yellow matter.

Second ovary pale, and destitute of vesicles, except at its distal extremity, where a number were clustered around an hypertrophied follicle, some projecting on the inner, and others on the outer surface of this bag, which was of the size of a grape.

2. M. C., married, and mother of a family. Death eleven days after parturition at full time. Both ovaries smaller than natural, and former cicatrices nearly faded. In one of the ovaries nothing was visible except a vesicle of the minutest size on the surface. In the other there was the same destitution of ovisacs; but the tubes and broad ligaments of both had several vesicles of a very delicate structure embedded in them; and in this ovary was one white body of small size, and also another body, which, when penetrated, gave issue to a little green fluid, and was found to consist of a thick, very white and shining

inner membrane, surrounded by a more delicate capsule, which was of a green colour, as if dyed by the effused fluid. After maceration for a couple of days in alum water, the dense white and glistening inner membrane could easily be insulated, when it appeared of the bulk of a pea, of the thickness of thick post paper, incapable of division into laminae, and diaphanous, except here and there, where it was more obscure. The bed of ovary from which this body had been raised was now found to exhibit some traces of the greenish colour, and to consist of an internal pulpy and delicate lining, which had been in immediate apposition with the exterior of the removed body, and of another stronger membrane, from the outside of which irregular and imperfect laminae of stroma could be separated. The pulpy appearance of the inner membrane seemed to be produced by the presence of minute sparse points of a more condensed tissue, like granular or cephaloid matter, deposited on its exterior.

3. ———, 22 years of age. Death from acute pleuritis and empyema, three weeks after delivery of first child.

Ovaries large, plump, smooth, and pale, with the exception of three nearly faded old cicatrices on one, another having a foramen, and several black points from Graafian vesicles advancing to surface. On cutting through the centre of this foramen, a body of about the size of a large garden pea was observed, having a white pellicle in its centre, and its periphery covered by a similar investment, the body itself consisting of a ring of about an eighth of an inch in thickness, of a red, inclining at margins to a somewhat yellow colour, of an oblong shape, and not distinguishable from the other parts of the ovary, which were all of a very red colour, except by its defined shape and deeper dye, it being destitute of any fibrous or of any convoluted appearance, and being situated between the two pellicles mentioned, but not having, either in them or in itself, any stellated configuration.

Three minute points in other ovary; one of a bright yellow, another white, with a small portion yellow, and the third a transparent pellicle enclosing a black point, apparently blood, decomposed and nearly absorbed. Numerous small Graafian vesicles in both ovaries,

but no capillary-sized foramina from these bursting on the surface could be detected.

4. ———. Died of phlebitis, three weeks after delivery at full time. Ovaries not affected by disease. Subject delicate.

External surface of both glands pretty copiously set with transparent eyes or points, some as small as the larger grains of sand, and others of the size of millets. Some had burst, leaving minute colourless pores in the peritoneal coat; in others the puncta were scarlet coloured, and had each a very delicate areola of the same hue; and in a third variety the blood in these areolar capillaries had been decomposed, and the parts had a sooty appearance, the discolourations being more or less annular, and having slender openings in their centres. In other respects the ovaries were smooth, the linear cicatrices of the menstruating period being nearly effaced. In each ovary was a cyst of the size of a swollen garden pea, consisting of an extremely white, dense, internal membrane, with polished, but fissured, inner and outer surfaces, arising from a degree of corrugation. This membrane was of the thickness of parchment, diaphanous, and had interposed between it and the substance of the gland, in both cases, two other delicate but distinct membranous layers, without there being a vestige of granular matter on either, or the possibility of raising any more laminae from the ovary enveloping them, or of distinguishing any difference in the structure or degree of organization of the two. She had been delivered, under the superintendence of Dr. Pagan, the Professor of Midwifery in the University, of a single child.

5. Mrs. ———, aged 26. Had a child four weeks before death from chronic visceral disease. Placenta, a portion of which in a friable pulverulent state remained, had adhered to posterior part of right cornu. Both tubes glued to ovaries, which were small and corrugated. A comparatively recent cicatrix was seen in right ovary, corresponding to which, internally, was a circular ring of rose-coloured tissue, which became very florid on the access of air, and consisted of a fibrous structure, of about two lines in thickness, with a transverse oblique arrangement of its capillary-sized fibrils, something like

what obtains in the walls of the left ventricle of the heart. Within this body, but not adherent to it either by vessels or prolongations of itself, was an opaque, yellowish-coloured hollow membrane. A vesicle, similar to what is often seen in the broad ligament, was found, a little distance from the ovary, within the folds of this membrane, and adjacent to the portion of fallopian tube, the pavillon of which adhered to the ovary: this appeared in every respect like a Graafian vesicle which had passed from the ovary to its new situation by interstitial absorption; and, when laid on a piece of glass, cut into two, and examined by Dr. Rainy, Professor of Medical Jurisprudence in the University, with the microscope, it was found to contain a granular membrane and an ovulum.

SECTION III.—*Ovaries of women who died within, or at, two months after delivery at the natural period.*

1. — —, aged 37 years, and mother of seven children, the youngest five weeks old. Uterus enlarged about a fourth; cavity large, and dyed with blood. Sinuses enlarged. Os uteri black, and epithelium abraded. Spermatie veins much varicosed, and occupied by laminated coagula arranged in spiral coils. Ovaries smaller than medium size, pale, and nearly smooth, particularly the *left*, which was also smaller, and which exhibited externally two small, raw-looking, and vascular, abraded spots of a minute size, as if occasioned by the rupture of small vesicles, which had risen above the surface of the peritoneal coat, and been discharged. Inner surface pale, with some very small Graafian vesicles in its parenchyma, but no rose-coloured, yellow, white, or black body.

Right ovary about medium size, with remains of four or five large-sized cicatrices, and the appearance of a number of miliary Graafian vesicles, many of them near and some within the inner surface of the peritoneum; while others had penetrated the entire thickness of this membrane, and remained either with a segment of the size of a small pin-head protruding externally, or had given way and been discharged, leaving puncta of a red colour. No vestige of any other form of ovarian body, except at one point, where there was an ill-defined corpus albidum.

2. — —, died of suppuration in uterus, &c., six weeks after delivery of what was said to have been her first child. Ovaries unaffected by disease. On one there were two cicatrices, one very well marked, and the other less, and a minute red point, as if occasioned by the adjacency of a Graafian vesicle; and on the other there was an indentation or central hollow point, surrounded by an annular condensation of the ovary. On laying the latter open, an elliptical cavity, corresponding to the central dimple or depression, lined by a white, opaque, pellicle, and surrounded by a condensed, extremely white, and somewhat gristly oval ring, in the situation of the external hardness, came into view, and for a little was supposed by Mr. Allan Burns, who assisted in the dissection, and by me, to be the vesicle from which the fecundated ovum had been discharged.

On cutting through the centre of the principal cicatrix in the other ovary, however, a body was brought into view corresponding also, with a feeling, externally, of a tumor, of about the size and shape of a dried pea, having a central white opaque membrane or pellicle, not admitting of division into layers, or exhibiting any appearance, when examined with this view in the most careful manner, and in different ways, of being capable of such division, but being about the diameter of a mustard-seed, and having white streaks proceeding from it into the substance of a ring, about an eighth of an inch thick, of a pale brownish or slightly reddish colour, having an oblique linear arrangement of its fibre, and a structure, in respect to consistency and colour, resembling the reddish, horny, condensed cuticle which surrounds some clavi. External to this ring, which became redder, and more like to pale muscle, on exposure to the air, there was a distinctly circumscribed, white, delicate ring of capsular investment.

The differences between the body just described, and that contained in the other ovary, were the smaller size of the central cavity, the more organized state of the ring, the presence in this of red fibres, and its shining, horny, and yet muscular look, intersected on its inner margin by white striae from the inner pellicle, and surrounded by a well-marked capsule of opaque membrane,

3. Mrs. C——, death eight weeks after accouchement of her third child.

One ovary.—A cicatrix, behind which was an elliptical body of about the size of a small pea, enveloped in a capsule, and presenting, when divided internally, a pulpy matter, which resembled in consistence the inner surface of the cephaloid cysts, only of a marked red colour from its great vascularity. Cavity obliterated. Six corrugated, hollow, white bodies in the two glands.

4. ———, aged 22. Death from suppuration in joints of pelvis, &c., eight weeks after birth of second child, the first being four years previous.

Right ovary larger than left. External surface marked with some nearly obliterated cicatrices, and the porous remains of some minute vesicles which had burst and been discharged. Subjacent to one of the nearly obliterated large cicatrices was an elliptical, slightly corrugated, and very white empty cyst, of about the size of a hemp-seed, the inner surface of which was of a shining pearly whiteness, destitute of any appreciable inner layer, and the whole thickness of its substance not more than that of thick paper.

In the *left ovary* were two bodies of a similar construction, but smaller and globular; they were whitish, empty, corrugated hollow cysts. In both ovaries there were a few small vesicles, filled with dark coagulated blood, but without any thickening of their coats. No other body of any kind.

5. ———, aged 37 years. Mother of four children, youngest of which two months old at death. Ovaries white, and although retaining the vestiges of numerous cicatrices, these were superficial and smooth from age. No appearance of Graafian vesicles either on surface or in texture of glands. One ovary contained a body of an elliptical form, and of about four lines in length, and nearly three in breadth, having a horny-looking, gray, semi-transparent, striated circumference, enclosing a minute, angular, or stellated, white-coloured central portion, or line. The striated marginal, or annular structure had much resemblance, in linear arrangement and fleshy colour, to the human nail as it rests on the subjacent pulp of the finger, and, when viewed by transmitted light, its tint was seen to depend on the presence of red vessels, and the striæ of its inner margin on the intersections of minute processes

of the inner membrane. This latter, similarly examined, was translucent, and consisted of a distinct delicate membrane, forming a minute cavity. Two white bodies in ovaries, of a yellowish fatty look, with external convolutions.

SECTION IV.—*Ovaries in women dying from two to three months after delivery at the natural term.*

1. Mrs. ———, aged 44 years. Youngest child ten weeks old.

On *one ovary* was a recent but thoroughly skinned cicatrix, and another which permitted a bristle to pass a very little way; and internally, there were various empty white cysts, from the size of a hemp-seed to that of a grain of mustard, two of which were connected with the recent scar and foramen. Gland two inches long by one broad.

Other ovary a third smaller. Remains of one large cicatrix. A minute vesicle and some punctuated abrasions of peritoneum on external surface, and, internally, some very small, but full Graafian vesicles. A number of white cartilaginous-like hollow bodies, all of small size, and one very little cyst with thin unchanged coats, but filled with clotted blood. No vestige of any other body.

2. Mrs. R——, aged 36. Death from typhus three months after birth of ninth child; being previous to fever in bad health. Ovaries of good size. *One* exhibited two small vesicles near to surface, and five cicatrices, old, and nearly filled up. On opening one of these, which was still raw, an empty Graafian vesicle was seen behind it, of nearly the size of a barley-corn, but without abnormal vascularity or thickening of its coats, or any clot.

Other ovary paler and smoother than the first, with two or three ecchymosed spots, as many faded scars, and one minute projecting vesicle; while, internally, the only things noticeable were some vesicles, and the imperfect remains of three white hollow globular bodies.

3. Mrs. M——, aged 32. Eight children, youngest three months. Ovaries shewed traces of old cicatrices, and in *one* of them, on which were also seen some small vesicles, these scars were more deeply indented than in the *other*, in which there were only some distended vesicles, and an obscure appearance of two "white bodies;" while

in the first there was, 1st, in centre of gland, a thin vesicle, and without any seen connection with a scar, having its coats dyed with a snuff-coloured paste of disorganised blood, which still lay on it. 2d, a white body; and 3d, a solid, well defined, oval body, which consisted of an external ring of very vascular, fleshy looking substance, as red as muscle, and a central opaque line.

SECTION V.—*Ovaries in individuals dying four months after natural delivery.*

1. Mrs. M'—, 35 years of age. Mother of six children; second youngest six years of age; youngest at breast four months old. Surface of *one ovary* white and smooth, with exception of superficial remains of a cicatrix, and several transparent vesicles of a very minute kind. On cutting through the former, a solid body, somewhat larger than a hemp-seed, came into view, of a reniform shape, with an elliptical central portion of about the eighth of an inch in breadth, of a whitish, opaque colour. This, which seemed to be the corrugated remains of the inner layer, was bisected in its long axis by a more translucent line, formed apparently by lymph, which had agglutinated its inner sides, and obliterated what was left of its cavity, while its circumference had a serrated arrangement, occasioned by delicate processes of itself shooting into an annular, more external body, of a transparent, fibrous, and delicate muscular looking tissue, and of a faint reddish colour, which, in its turn, was invested with a capsule, from which red vessels penetrated to the annular portion.

Other ovary filled with unbroken vesicles, and contained also an empty follicle of the size of a pea, having its coats, which remained thin, painted internally with a thin coating of yellow matter supposed to be decomposed blood.

2. ——. Mother of two children; youngest sixteen weeks old. The *one ovary* exhibited one or two faint cicatrices, and the *other* the remains of a circular abrasion, of the size of a small segment of a dried pea, in which was a foramen leading into a cyst of the bulk of a garden-pea, which contained a clot of blood as large as a hemp-seed. The inner surface of this sac, consisted of a yellow pulp, of considerable thickness, which could be scraped off, leaving a

vascular envelope, itself surrounded by a capsular investment, and which two unitedly, resembled one of the white bodies. There was a similar cyst, but only half the size, and empty of blood, in the opposite side of the gland, and the other ovary contained minute miliary ovisacs only, although these were abundant.

3. ———, a child sixteen weeks before death. Both ovaries white, and free from old linear scars, there being present only two or three recent minute pory solutions of the peritoneum, and on each gland a reddish or rose-coloured spot, and some hardness; corresponding to which there was, in the one ovary, a circular, solid mass as large nearly as a small dried pea, having a reddish colour, and a white, stellated, circular centre; and, in the other, an empty Graafian vesicle with thin coats and a yellow deposit on inner surface, and several melanotic spots, or corpora nigra.

4. ———, aged 37 years. Seven children; youngest four months old. Ovaries well developed.

One ovary. Peritoneal coat smooth, and presenting at several places vascular spots, each of the size of a pin-head, which were found to proceed from turgid Graafian vesicles escaped from the parenchyma, and lying with thin naked coats immediately under the surface, which was diaphanous. At two points of this kind the peritoneum was absorbed for about half the extent of the subjacent vesicle. Internally, the gland was very full of large vascular vesicles, and a circular hard body, moveable in the stroma, and of the size of a small pea, exhibiting when cut the whitish yellow, shining, cartilaginous tissue of the corrugated empty cysts, which I have called dense white bodies, was seen.

Other ovary presented two dark spots indicating subjacent unbroken Graafian vesicles moving to surface, and a third in which a minute portion of the hemisphere of a vesicle had already risen above the level of the peritoneal coat; also, a transverse groove across the free edge of the gland, arising from the protrusion of the half of a circular body of a cartilaginous appearance, being, when cut into, hollow, empty, of a vascular tissue, and of a dull whitish red colour; also, immediately adjacent to this was another circular, small, flat, hardness, which was connected with

the presence of an empty, hollow, very white body, which was not vascular.

5. —, aged 24. Child four months old. Inner surface of cavity of uterus occupied by a highly injected vascular net-work, which was painted over with a thin layer of the white fluid of the tubes, which also were very vascular.

Right ovary exhibited two points, at each of which a minute segment of an unbroken, vascular, miliary sized Graafian vesicle was seen presenting through a foramen of the peritoneal coat; also, several small cicatrices and hardened points, under which, internally, were white bodies of the size of mustard seed.

Left ovary. Two very strongly marked, but old cicatrices, corresponding to one of which was a solid, shining, white body, and to the other, an ink-coloured thin vesicle, with its inner membrane gathered up into delicate rugæ.

ON

THE DOUBLE SALTS OF IRON.

(For the Medical Gazette.)

[Concluded from page 840.]

In Case 1, hydrated sesquioxide of iron was added to a boiling and concentrated solution of citric acid: it was observed to dissolve readily and in large quantity up to a certain point. A further addition left the solution turbid, apparently from excess of oxide. The mixture was now suffered to cool, was then filtered, evaporated to a treacly consistence, and dried in thin layers on well glazed earthenware: it separated in lamellæ of an acicular form and garnet colour, scarcely soluble in cold water, but more readily in hot. Fifty grains of this salt, dried at 212° , were examined as to the quantity of oxide contained; it yielded fourteen grains = 28 per cent. Another portion, prepared after the same manner, yielded fifteen grains = 30 per cent.

In Case 2, two several quantities of citric acid and hydrated sesquioxide of iron were kept at a temperature just sufficient to influence to combination until chemical action had ceased. The solutions were filtered, reduced, and dried, as in Case 1. The salts sepa-

rated in lamellæ, but of a short and broad sort; these were in like manner submitted to examination, when there were found in one 22 grains of oxide, and in the other 25 grains of oxide, per cent.

In Case 3 I proceeded as in Case 1, until the whole of the oxide derived by precipitation from four parts and a half of commercial sesquioxide had been added to five parts and a half of crystallized citric acid, and gentle ebullition was continued for fifteen or twenty minutes. In appearance much of the oxide remained unchanged; but it was evidently in combination, for on the addition of an alkali it was totally and instantly dissolved. Owing to the variable quantity of real oxide existing in the article sold in the shops, this experiment will not be uniformly successful. From an experiment which will be detailed in a subsequent part of this paper, this combination of oxide of iron and citric acid will be inferred to be in the ratio of 80 to 140, or of one equivalent of oxide of iron to two equivalents of crystallized citric acid.

In case 4, tartaric acid was substituted for citric, and subjected to the same treatment as described in case 1. As soon as the solution appeared turbid one half was removed, filtered, and dried at 212° , when one hundred grains were found to be impregnated with twenty-six grains of sesquioxide of iron. I did not repeat this experiment. To the remaining half more oxide was added, and during the continuance of this part of the operation a bulky hydrated bitartrate of iron was thrown down, very nearly resembling hydrated sesquioxide of iron, but differing in being totally soluble in alkalis: this precipitate was well washed and dried at a gentle heat, which was raised towards the close of the process to 212° , and there kept until it ceased to lose in weight. One hundred grains were then heated to redness; it first evolved a suffocating inflammable vapour, then charred, and finally left me thirty-seven and a half grains of residue: the residue was dissolved in nitro-hydrochloric acid, precipitated with caustic ammonia, and washed. It was again heated to redness, when there were found to be thirty six grains nearly.*

* It is stated in Rose's Manual of Analytical Chemistry, that ammonia completely precipitates sesquioxide of iron from its solution in aqua

In case 5, acetic acid was digested at a common temperature with the hydrated oxide; union was readily effected; and by adding a little alcohol, and filtering, a beautiful solution was obtained, which after a lapse of months had only a very trifling deposit. A quantity of this solution was left to spontaneous evaporation in divided portions of say half an ounce each; the great bulk suffered decomposition in drying, and I only obtained from a pint of solution about one scruple in a perfect state, and about as much more in a slightly imperfect* condition. The perfect salt is in lamellæ of a ruby colour, and is soluble in water: ammonia precipitates oxide of iron from its solution, and the affinity between the oxide and acid is so trivial, that a little elevation of temperature is sufficient to overbalance it: in its dry state it will bear considerable heat without alteration: before examination I held it some minutes very near to a common fire. The twenty grains of *slightly* imperfect salt were made up to twenty-five, and heated to redness: after fifteen minutes it was found to weigh eight grains: the remainder was preserved, as I did not like to part with the very little that was with difficulty obtained.

It appears to me that the nature of the precipitate soluble in alkalis spoken of in cases 3 and 4, has been mistaken, and that they have been confounded with the oxide of iron itself. I some while ago met with an observation, but have failed to discover it since, to this effect—"the further addition of oxide (meaning addition after solution had ceased), causes the separation even of that portion which had been previously dissolved." A writer in the *Pharmaceutical Journal*, Vol. I. p. 595, says, "let the oxide be added in excess." M. Beral also directs that "rather more oxide should be added than the acid will dissolve." Whatever may be the value of these remarks, or how much they may conflict with each other, it is not my present business to inquire; I refer to them, because individually, and together, they do seem to imply that the fact of the oxide combining after

solution had ceased has been overlooked; and possibly to the prevalence of this oversight we may attribute much of the erroneous impression which so generally obtains. On a further comparison, I find that more of these results are not coincident with the opinions of some others: the writer in the *Pharmaceutical Journal*, to whose paper I have alluded, after a description of M. Beral's process, has the following—"The oxide of iron and citric acid combine in the proportion of forty parts of the oxide to seventy of the crystallized acid." The same is repeated by Dr. A. T. Thomson, in the last edition of his work on *Materia Medica*. I have repeatedly tried, without success, but with some uniformity as to result, to obtain a citrate of iron in scales so constituted; and as these proportions seem more fitly to apply to a compound of a different description, I would respectfully leave to these gentlemen to determine whether some error in computation may not have attended their investigations.

Regarding what has been stated in the preceding cases as matter of evidence, I see not how to escape from the conclusion, that in case 3, and latter part of case 4, we are presented with definite compounds of sesquioxide of iron with citric and tartaric acids: indeed, the constitution of the tartaric acid salts determined theoretically, and by experiment, agreed so very closely, as to leave little room for dispute, and with the citric acid salt it is not much more discordant. The combination of the oxide with acetic acid is also to be considered as definite; inasmuch as all acid uncombined must have escaped during the evaporation. The quantity of oxide in twenty-five grains of the dry salt held a few minutes before the fire was found to be nearly eight grains, but this estimate, owing to causes before mentioned, is a trifle too high: now, by a theoretical computation, a salt composed of four equivalents of acetic acid, and one equivalent of oxide of iron, should contain seven grains (rather more than less) of oxide in the same quantity; which, therefore, is probably the actual constitution of the article in question.

But it may fairly be doubted whether the products of the first and second operations have an equivalent constitution; the examination did not corroborate

regia: an impression is now gaining ground that such a statement is inaccurate.

* The imperfection consisted in minute opaque dull spots, arising from disengagement of acetic acid, and deposition of oxide.

such an idea : nevertheless, both a ter-citrate and quadricitrate may exist ; and the latter supposition gains support from the probability of acetic acid combining in the same proportion.

Sesquioxide of iron is not precipitated from its combination with citric and tartaric acids, by alkalies, alkaloids, earthy and some metallic oxides : according to Professor Brande, malic, mucic, kinic, and peptic acids, lead to the same result. It has been found that double salts are formed, the precise constitution of which chemists are by no means agreed on : my own observations induce me to regard a binary series, the existence of which I will endeavour to demonstrate.

I took bicitrate of ammonia, and to its boiling solution added hydrated oxide of iron so long as a *greenish yellow* colour was retained, or so long as a distinct *red* absented itself : the solution must be boiled a few moments after each addition of oxide, or the effect will not be observed : when the process is complete we have a combination of one equivalent of bicitrate of iron with two equivalents of citrate of ammonia. I obtained from one specimen so made very nearly twenty-two grains of oxide per cent., and from another twenty-four grains : it dries in scales of a golden colour.

Again, I took the precipitated oxide derived from four parts and a half of commercial sesquioxide, and boiled it with five parts and a half of crystallized citric acid, and after continuing ebullition a short time it was supersaturated with caustic ammonia ; it was then filtered, and cooled quickly, and I had a solution most difficult to evaporate without decomposition, but which, when dry, was perfectly soluble : one hundred grains of this salt afforded me nearly thirty-six grains of oxide of iron. I am sorry to say, another gentleman, to whom I gave a portion of this salt, only obtained thirty-four grains : pardon my attaching importance to this circumstance. It was my request that before examination notice should be taken that the salt was dry, for it is of so deliquescent a nature that by long keeping, or transferring from one bottle to another, it absorbs water. I was sorry therefore to find, by his note to me, that he had tried the salt in the state I sent it to him. It is true, he remarked, that the salt

appeared quite dry, but there might have been water ; and my impression is there was, and that his estimate is too low : under the circumstances, I think I am entitled to split the difference, and call it thirty-five.

I submit it to you whether I may not with reason infer that the real constitution of this salt is one equivalent of citrate of iron, and one equivalent of citrate of ammonia ; that is,

Sesquioxide of Iron	80	or	37.56
Citric Acid	116	„	54.46
And Ammonia	17	„	7.98

Equivalent	213	100.00
------------	-----	--------

What now forces itself upon the mind—what but the conviction that these two compounds are the representatives of two distinct series of chalybeate salts ? I anticipate the objection that I do not show by analysis that my theory is exactly confirmed. It is true I come only very near the point, but I ask, let it be recollected that these salts are uncrystallizable : that on this account it is most difficult to keep the one series from interfering with the other ; and this practical difficulty has been the cause, I think, of the uncertainty of opinion that is current amongst us. I shew two compounds, one containing very nearly one equivalent of oxide of iron united to one equivalent of acid, the other containing one equivalent of oxide of iron united to two equivalents of acid ; they have peculiar external characters, and are arrived at by different means. I point out how this “not quite” is to be explained, and I do think that in forming my opinion I have followed closely in the track of inductive science : I determined to rest the preceding part of my argument on what, with all the correction I have bestowed on it, still remains weak and defective, because, trusting to my formula, I had given to several gentlemen samples of a salt which proved to be less perfect than I have made it at other times. This difficulty, which opposes itself to the establishment of a superseries among citric acid salts, will not be felt when I come to treat of the analogous compounds with tartaric acid. We have been long familiar with an example of the inferior series of tartaric acid salts in the officinal potassio-tartrate of iron ; I therefore shall not now further occupy myself with them. The superseries is

made evident in the following manner. The bitartrate of iron resulting from the operation in case 4 is to be saturated with potash or ammonia; the solution is to be then filtered and carefully dried in small quantities at a time: I found ammoniacal salt to contain thirty-five grains of oxide: estimated theoretically, it is a fraction short of this quantity. Thus—

One equivalent of oxide of iron	80	or	34.93
Two equivalents of tartaric acid	132	or	57.64
One equivalent of ammonia	17	or	7.43
	229		100.00

To one or other of these two series, or to a mixture of both, the whole of the double iron salts, containing the sesquioxide, with which I am acquainted, are capable of being referred. The difficulty attending the manufacture of perfect salts of the superseries is such as to render it improbable that they can ever become extensively used. The ammonio-citrate of commerce contains an average of thirty per cent. of oxide; and in this state it is more permanent. A salt having this constitution is made without much trouble as follows*:

Take a bisalt of any third constituent

* The preparation of the hydrated oxide is an important point in the formation of these salts; the London College orders the sesquichloride to be decomposed with caustic potash; the Edinburgh directs the persulphate to be similarly treated with caustic ammonia. My own plan in detail differs from both of these. I make a solution of the sesquichloride according to the directions of the London College, adding nitric acid to insure the complete peroxidation of the iron, but instead of decomposing cold, diluted, and with a caustic alkali, I mix the solutions warm, somewhat concentrated, and use a carbonated alkali, and for these reasons: a moderate degree of heat is favourable to chemical action, and when conjointly with this double elective affinities are in operation, decomposition is more complete, and the liability to form a basic salt is considerably diminished. Again, if the solution is very weak, the precipitate will be of so buoyant a nature that the process of ablation will be tedious. As soon, however, as the oxide is precipitated, longer retention of heat is absolutely mischievous, and large quantities of cold water must be added without delay, and the washing continued until the supernatant liquor is tasteless: the remaining water being drained off, the oxide is ready. To this it has been objected, that carbonic acid has no affinity for sesquioxide of iron. I apprehend that affinity does exist, although ordinarily it does not influence to combination: how else shall we explain the fact, that solutions of sesquicarbonate of ammonia and bicarbonate of potash dissolve, under pressure of carbonic acid, sesquioxide of iron? That an affinity exists, I think is manifest; and that it prevents failure in making the hydrated oxide I am inclined to believe: at all events, I have not formed a basic salt since I have adopted the plan of decomposing with carbonate of ammonia.

(bicitrate of ammonia, for example), made by adding a known quantity of citric acid to a similar quantity exactly neutralized with ammonia. This solution, in its turn, is to be saturated with hydrated oxide, which is accomplished by mixing the oxides gradually so long as it continues to be dissolved, avoiding any great excess. This formula admits of very general application by simply changing the acid or the third constituent, but there are exceptions.

Dr. A. T. Thomson observes on the ammoniacal citrate, that it disagrees with some constitutions more than its congener the potassio-tartrate. Guided by this opinion, I would direct attention to the compound of tartaric acid, iron, and potash, obtained by dissolving the hydrated bitartrate in a solution of the caustic alkali: if they be mixed in such proportion as to keep the bitartrate slightly in excess, supersaturating at the end with ammonia, a salt will be obtained perfectly but slowly soluble in cold water, substantially consisting of tartaric acid, iron, and potash, and belonging to the superseries of double salts. The admixture of ammonia is advised, first, because it is impossible to separate any excess of potash, should there be any; and, secondly, because it is difficult to effect complete combination without such excess.

In pursuing this investigation, the present nomenclature of the Pharmacopœia seemed incapable of comprehending the double series which opened itself to view; and on searching for a better, I soon found myself on ground which was occupied by contending parties. The unsettled point consisted in this: is the iron, or the third constituent, to become the adjective adjunct to the acid? In other words, is a compound of tartaric acid, oxide of iron, and potash, to be called potassio-tartrate of iron, or ferro-tartrate of potash? Many, whose names command the greatest respect, continue to make the third constituent express the quality of the acid; and these have custom for their stay. On the other hand, it is contended that this nomenclature conveys erroneous impressions of the constitution of the salt; and the argument is thus summed up by Dr. Pereira, in his *Elements of Materia Medica*. "The ferro-tartrate of potash is to be regarded as a double salt, in which

tartrate of iron is the acid or electro-negative ingredient, and tartrate of potash the electro-positive or basic constituent. On this view we comprehend why ferro-cyanide of potassium and the alkalies refuse to act on it in the way they do on the ordinary ferruginous salts until an acid be added." But the author, in adopting a nomenclature, leaves the double *protosalts* unprovided for. If, then, the electric condition of these oxides is such that we are obliged to regard them in the light of acids rather than bases, it seems consistent that, with Berzelius, we should apply the usual termination of acids to them. Acting on this suggestion, the class of double-chalybeate salts would resolve itself into—

Ferrie or *sesquioxide* salts,

Ferroso-Ferrie or magnetic oxide salts,
And ferrous or *protoxide* salts.

The ferrie salts would be subdivided into true ferrie, or such as have *one* equivalent of oxide united to *one* equivalent of acid; and diferrie salts, or such as have *one* equivalent of oxide united to *two* equivalents of acid. The name of the one would then be ferrico-citrate of ammonia; of the other, diferrico-citrate of ammonia.

I now close my remarks on the combination of iron, to which I may return at no distant period, should it be admissible. I have endeavoured to assign reasons for opinions; but as the subject is one of great difficulty, I feel myself proportionately diffident. That I have established, to the satisfaction of others, what appears evident to myself, I dare scarcely hope; nevertheless I do hope that what I have said will lead the way to a satisfactory settlement of the question; and if I have accomplished this, I shall not unworthily have occupied a space in your journal.

I am, with respect,

Your obedient servant,

W. HEMINGWAY.

NOTES ON MENSTRUATION.

To the Editor of the Medical Gazette.

Sir,

IF you consider the annexed "Notes on Menstruation" worth attention, you will perhaps do me the favour to insert

them in an early number of your valuable journal.—I am, sir,

Your obedient servant,

JOHN WARWICK.

23, Hatton Garden,
March 11, 1841.

All the systematic treatises on physiology agree in describing the menstrual fluid "to consist of blood deprived of its fibrin; the fluid being composed of serum, in which red corpuscles are suspended."*

The opinion that fibrin is absent or deficient in the menstrual blood, has obtained universal currency during the last thirty years, upon the authority of MM. Brandet and Lavagna.†

Previously to this period, it does not appear that any such opinion had been entertained. Mauriceau‡ expressly states, that the menstrual blood "commonly differs in no way from that which continues in a woman's body." Haller|| makes the same remark, and J. Hunter¶ terms menstruation "a natural evacuation of blood."

The fact that unaltered corpuscles are present in the menstrual fluid was known to J. Hunter, who remarks, "the red globules, however, are not dissolved, they retain their figure * * ." More recent observations confirm this. Dr. Donné having submitted to careful microscopic examination portions of the menstrual fluid obtained from two healthy females, found it to contain: 1, common blood globules of the proper character, and in great abundance; 2, mucus from the vagina, mixed with epithelial scales; 3, globules of mucus from the cervix uteri††.

Professor Schultz‡‡ examined a tea-

spoonful of the fluid collected from a healthy female. He describes the vesicles as separating and sinking to the bottom of the fluid, where they formed what seemed "to the naked eye a cheese-like coagulum. Observed through the microscope, this apparent coagulum was found to be composed of perfect vesicles heaped together, yet isolated, and not adherent to each other, as easily happens to the vesicles in living arterial and venous blood*."

It is certain, then, that the menstrual fluid contains numerous perfectly natural blood corpuscles†. The foregoing statements, recording the retrospective results of chemical analysis and microscopic examination, are commonly found together, as in the paragraph above quoted. Nevertheless, with due deference to authority, it appears to me that these statements involve a contradiction in sense. The objection is, that we do not observe any secretive process, or process analogous to secretion, which could so act upon the blood as to strain the liquor sanguinis of its fibrin, and at the same time permit the free passage of its unchanged corpuscles.

Therefore, with the knowledge that the menstrual fluid contains the common blood corpuscles, we might conclude *à priori* that it would also contain a due proportion of fibrin.

Recent analyses of the fluid confirm this conclusion as truth. M. Bouchardat, upon analysing a portion collected in a state of purity by means of a speculum fitted around the cervix uteri, found it to be composed of the ordinary ingredients of the blood, arranged and combined in arterial proportions. This satisfactorily confirmed the previous observations made by Mr. Denis, from which he had concluded that the pure menstrual fluid was identical with arterial blood.‡ The researches of MM. Retzius and J. Müller,§ have also decided the presence of a full quantity of fibrin.

Furthermore, the catamenial dis-

charge is commonly described as "being readily distinguishable from true blood by its want of power to clot;"* and this want of coagulation is regarded to result from the absence of fibrin, and is in turn cited as evidence of such being a fact.†

However, now that we are assured of the existence of fibrin in the menstrual fluid, we must look elsewhere to discover the reason of its non-coagulation. But firstly, does it always fail to coagulate?

There is good reason to believe that such is not always the case. M. Brierre de Boismont in describing the menstrual fluid observes, that "after some time it divides into serum and clot,"‡ and furthermore says, "the clots (in the menstrual blood) are incontestible, the coagulation not to be rejected; for the researches we have made on this point have shewn us in many cases the presence of clots."§ Moreover, coagula have been often found in the uterus of women dying during the menstrual period.||

Yet, as a general rule, it is probably correct to say, that the menstrual fluid does not clot, and we have therefore to inquire by what circumstance the coagulation of the fibrin is prevented.

This, in the opinion of Hunter, was the loss of vitality. "There is," he says, "a natural action of the living body which destroys the life of the blood in the act of extravasation; this is the discharge of the menses in women:"¶ and again, he elsewhere describes menstruation as an action by which "the blood loses the principle of coagulation, and I suppose life;"** but he offers no explanation of the mode in which, as he imagined, the death of the blood takes place.

M. Retzius has attributed the non-coagulability of the menstrual fluid to the presence of the phosphoric and lactic acids, which he supposed to be developed in the uterine vessels.**

But M. Retzius is in error on this point, for the pure menstrual fluid is as alkaline as the rest of the blood, and

†† Loc. cit.

acquires acidity by admixture with the secretions of the vagina, which have been found uniformly acid in healthy women.*

From the foregoing observations I am led to conclude, that the non-coagulation in general of the menstrual blood is owing, 1st, to an impaired vitality consequent upon the slow process of its elimination; and 2dly, to its mixture with the mucus of the vagina.

In support of which conclusions, I refer respectively to the observations of Professor Schultz, upon the indiscriminate deposition and want of cohesion of the corpuscles; and to the experiments of M. Mandl upon the effect of admixture with different secretions in retarding or preventing the coagulation of the blood †

From its mingling with the mucus of the vagina the menstrual fluid acquires also the odour, dull colour, turbidness, viscosity, and other qualities, which have been commonly considered as indicative of its peculiar character.

It follows from the foregoing considerations:—

1st. That the pure menstrual fluid is ordinary blood.

And 2dly. That it is not a secretion, but simply a sanguineous exhalation; ‡ in fact, a hæmorrhage which differs in no respect from an ordinary hæmorrhage.

I would therefore define the simple act of menstruation to be “a periodic constitutional hæmorrhage from the inner surface of the uterus.”

The proximate cause of this hæmorrhage is an element common to all spontaneous hæmorrhages, namely, a local hyperæmia, or congested condition of the vessels of the part from which the blood is effused.

(The increased vascularity of the uterus during the menstrual period is sufficiently obvious after death. There is an indifferent representation of this in Dr. Hooper's *Morb. Anat. of Uterus*, plate I., fig. 2. The same condition is found during life. Mons. B. de Boismont describes the cervix uteri as hot, soft, and tumid to the touch, and the lips so swollen as nearly to obliterate the os tincæ. On examining with the

speculum he found the vagina unusually vascular, the cervix uteri obviously enlarged, and having a bright red colour, very different from its usual pink or violet hue: from these appearances he considers the uterus to be in a state ‘de gonflement, d'engorgement et de pléthore.’*)

Its ultimate cause, that is, the exciting cause of the congestion, is now proved, beyond all reasonable doubt, to be the periodical maturation and discharge of a Graafian vesicle or ovum from the ovary.†

These two conditions constitute the total of local actions upon which menstruation depends. Therefore, an in-

quiry into the final nature of menstruation resolves itself into an examination of these two conditions.

This connection between the periodic congestion of the vessels of the uterus, and the maturation and discharge of a vesicle from the ovary, may be considered to obtain, either from the local proximity of these organs, or from their correspondence in function.

If we adopt the former view, and consider the congestion of the uterus to occur in consequence merely of its vascular communication with the ovary, we must then regard its congestion as an accidental condition. And here would terminate the inquiry.

If we adopt the latter view, and consider the congestion of the uterus to occur as an independent action, entered into for a particular purpose, and connected with the action of the ovary only by functional relation, it then remains for us to discover what this particular purpose is.

In answer to this inquiry, it may be advanced that the purport of the congestion is, in fact, the effusion of the menstrual blood.

But I must decline accepting this opinion, unless it should be accompanied by some rational explanation of the necessity or utility of the menstrual discharge as a distinct function. For it is at present difficult to explain what influence on the female system can result from the periodical evacuation of so small a quantity of blood in so gradual a manner. Neither can I consider the congestion of the uterus to result simply from its vascular connexion with the ovary. On the contrary, I am disposed to regard the periodic increase of vascularity in the uterus as an individual act of the organ, determined for a specific purpose—which purpose is the formation of the *membrana decidua*.

This explanation was first proposed by Dr. John Power, who defines the efficient cause of menstruation to be “an imperfect or disappointed action of the uterus in the formation of the decidua membrane*.”

This opinion has hitherto remained unnoticed, but it certainly deserves attention; and I purpose, at an early opportunity, to consider the evidences upon which it rests.

ACCOUNT OF THE

STRUCTURE OF THE CEREBELLUM.

To the Editor of the Medical Gazette.

SIR,

IF you consider the accompanying paper to fulfil, in some degree, the object for which it has been written, perhaps you will allow it a place in your journal. It has no pretensions whatever to original discovery, but merely professes to remove some difficulties, and put in a more intelligible form the account which has been given by others. I am quite conscious that in appearing to differ from such high authorities as Professor Reid and Mr. Mayo, I must incur the charge of presumption, but as it is generally allowed that the account above alluded to is by no means easy of comprehension, I would willingly admit that I may have mistaken his meaning, though both to others and myself the obvious interpretation seems to be such as I have stated; at least, if the description which I have given be confirmed by others, it will, I think, be of service to the inquiring student, as many, I know, have found it difficult, if not impossible, to cross this “*pons assinorum*.”

In conclusion, I may state that I have shewn my preparations to my respected teacher, Mr. Tatum, who allows me to say that he considers them to confirm the points I have attempted to prove. I must also acknowledge the kind assistance I have received from my friend and fellow-student, Mr. Henry Acland, to whom I was entirely indebted for the original idea of the structure.—I remain, sir,

Your obedient servant,

C. HANDFIELD JONES,

M. B. Cantab.; Prosector at St. George's Hospital School.

P.S.—I need hardly mention that I shall be most happy to shew the preparations I have made to any one who may wish to see them.

The laminae are the ultimate subdivisions of the folded surface of grey matter, which constitutes the exterior of the cerebellum; they are perfectly analogous to the convolutions of the cerebral hemispheres, and appear to consist of the same constituent parts. Since, then, on the exterior we have a

layer of cineritious substance, above 1-10th inch in thickness, (this is seen in a vertical section of any part to contain in its fold a central white line, which is evidently continuous with the white matter of the interior of the lobule to which it belongs), at the base of the lamina where the central white line joins the stem, a kind of enlargement, which marks the situation of the articulation, is observed to exist. We have now to inquire into the constitution of the central white streak. If, then, we take a lobule with several laminae on one side, and endeavour to raise one, we find that it adheres to the one above, and that we must rupture the grey matter and a medullary plate beneath, before it will admit of being drawn downwards towards the base of the lobule: in the same manner, if we attempt to pass it upwards, we have to rupture a medullary plate before we can carry the fissure up the axis of the one above, *i. e.* nearer the apex. Here, then, it is evident we have a medullary *commissural* plate on each side, running from the middle lamina to the one above, and to the one also below: these exactly accord with Professor Reid's account, and with Mr. Mayo's figures. But besides these, if the medullary commissural plate connecting a lamina with the one above be broken through, the lamina may be pressed downwards towards the base of the lobule, carrying a medullary plate with it, as well as all the other laminae which are nearer the base, with their medullary plates (*vide* Preparation I.), or if an interval be struck between the medullary plates of the stem of a lobule, and the fissure carried upwards, it will be found, unless taken in the axis of the lobule, to turn short off, and to enter a lamina (*vide* Preparation II.) Now these facts seem to shew, in the words of Reid, that "intermediately, between the external (commissural) plates, other medullary plates," derived, as I conceive, from the nucleus of the cerebellum itself through the stems of the lobules, "enter each lamina." At the centre of the base of the lamina we find an angular furrow, which receives a delicate ridge, situate on the medullary plate below: this disposition, to which the name of "articulation" has been given, will be better examined when we come to the lobules, being there much larger and more distinct.

The lamina may be easily unfolded by continuing the separation up its axis from the furrow at the base. The next part for our consideration is the lobule, which simply consists of an aggregation of laminae, placed somewhat in the manner of grapes upon a central stalk: this stalk or stem is chiefly made up of the medullary plates derived from the nucleus, which are proceeding to each lamina: near the base, however, of the lobule, external plates are found which may be traced reflected up the contiguous surface of the one adjoining (*vide* Preparation VI.): each lobule may be split up in its axis to the apex, or the fissure may be carried between the medullary plates, more to one side, when it will be found to enter a minor lobule or lamina (*vide* Preparation III.) We now come to describe particularly the "articulation," and this we shall do as it exists either in a lobe or lobule, for the lobules are not always articulated to the stem of a lobe, but, as in the case of the square lobe, directly on the nucleus. In a preparation before me (No. IV.), where the separation took place accidentally, the ridge is seen as a distinct rising, gently sloping on one side, but abrupt and concave on the other, which receives the under part of a minor lobule. From this ridge I can perceive no medullary plates ascending into the lobe which is seated upon it. The medullary stem seems to come principally from a part further back, *i. e.* nearer to the source from whence the medullary plates are derived. The furrow at the base of the lobe or lobule does not appear to be exactly in the centre, but considerably more to the *distal* side; hence the boundaries of this furrow would appear to be the central medullary plates which are derived from the nucleus, and are ascending into the laminae on the *proximal** side, and the commissural external plates which are passing to the next lobule on the *distal* side. The fissure made by continuing the separation from the furrow will sometimes pass up to the apex of the lobule, sometimes turn aside into a lamina. The cause of this we shall presently consider.

* "Proximal" refers to the side next to the point from which the medullary layers begin their course as they quit the nucleus, and is therefore *anterior*. "Distal" being the opposite, and therefore more remote, or *posterior*.

Let us now proceed to trace the course of the medullary layers which form the stem of the lobes. If one of these be broken off, which, we will suppose, bears a series of minor lobules on one surface, viz., the "proximal," and on the other several much smaller lobules and laminae, as in preparation VI., and we then strike a fissure in the medullary stem at the base of the lobe near to its proximal side, we shall find that by using a little pressure we can make the fissure run on, and if taken at the proper level, enter the lobule situated nearest the base, which may then be split up; again, taking a deeper level, and carrying a second fissure upwards, it will enter and divide the stem of the next lobule, and so on: thus we may proceed to split up the whole medullary stem of the lobe into its several layers belonging to each lobule. From this, then, we may draw the general conclusion, that the lobules are furnished with their medullary stems in succession by the mere giving off of the layers which compose the primary stem. This observation seems to render it quite impossible that the ridges for these lobules can exist on any one surface; for as the medullary layers are peeled up from the surface towards the centre, in the order of their superposition, so the ridges that exist upon them must necessarily be at different levels: this, of course, has reference to the free apices of the ridges, for the medullary layers are indented in the ridge for some depth. It is almost impossible, in following the fissures as I have above described, to light upon the exact interspace of the ridge and furrow with any certainty; or, in other words, to open the "articulation." In one instance (No. VII.) where this had occurred, a fissure is seen extending up the lobule the second in order from the base of the lobe; while a second fissure having been taken a little deeper, exposes the ridge received into the furrow above, and the last medullary plate, proceeding as it seems to the last lamina on the distal side of the lobule. In this preparation is seen also the commissured plate, running to the lamina immediately beyond the lobule. From this, as well as from No. IV., it seems evident that no medullary plates enter a lobule from its *own* supporting ridge; they all appear to come from the one *preceding*. It

may perhaps aid the mind to form a just notion of the ridge, if we conceive it to be the necessary result of the perfect apposition of the medullary plates, which, having run together for some distance, on arriving at the base of a certain lobule are about to separate; and while the upper stratum, destined for the laminae of that lobule, mounts up into it, constituting the stem, the next beneath, as if reluctant to quit its former companion, passes up a short way, forming the ridge, and then passes on to its own lobule, the next in succession. Another preparation (VIII.) may further illustrate this subject. A lobule is split at two levels; the first fissure opens into a minor lobule near the apex: the second runs up into the apex itself, and in so doing crosses the ridge on which the minor lobule is placed, but deeper than in the preceding; so that the free apex of the ridge is not visible, which exists on that medullary plate which proceeds to the laminae nearest the minor lobule. This seems further to confirm the above-mentioned idea, that the ridge is solely produced by the perfect apposition of the plates to each other. We must note here that, in following these fissures, it frequently occurs that they do not follow the same course on both sides of even a very narrow section, but (as in Preparation IX.) enter one lobule on one side, and a different one on the other. The cause of this probably is, that the medullary plates do not all lie exactly parallel, but sometimes decussate each other. This remark brings us back to a point we before mentioned, viz. the course of the fissure formed by continuing the separation from the furrow: this we stated seemed to vary; but in many instances it certainly runs up to the apex of the lobule: how then, it may be asked, are the laminae of the distal side of the lobule to receive their medullary plates? This was a great difficulty for a long time; but I believe I have now completely made out that, in every such instance, medullary plates will be found passing across the fissure to enter the laminae on the opposite side, though, from their great tenuity, they may, as they are broken across, easily escape observation. These decussating plates are seen in Preparation XII.

We now come, lastly, to examine the

course which the medullary plates take as they proceed from the central nucleus to enter the lobes. Now here I can only say that, in every attempt I have made, commencing the fissure at the semilunar notch, and carrying it backwards, the arrangement has appeared to be exactly analogous to what occurs in the medullary stem of a lobe; that is to say, successive divisions of the medullary nucleus pass off to enter each lobe in succession, and constitute its medullary stem, which is then further subdivided in the way we have seen. There is this peculiarity, however, that in the central nucleus the medullary plates decussate each other much more frequently, and seem as if they had not yet attained their regular order of superposition. From this it seems impossible that any "laminated stratum" can exist, as the "exterior shell of the nucleus," and the arrangement above described, is simple and

intelligible, and consonant both with analogy and with all our received ideas of the structure of nervous centres. With respect to the "corpus ciliare," the plates seem to enclose and surround it, rather than run through it: it is probably a similar arrangement to the "olivary body" of the "medulla oblongata," and is similarly surrounded by fibres.

Finally, in reviewing this simple and beautiful structure, we cannot but be struck by its exact analogy to what we observe in the cerebrum: the convolutions of the hemispheres correspond to the laminae, the superior longitudinal commissure, and the shorter ones from convolution to convolution, to the various commissural plates of laminae and lobules; and the radiating fibres of the crura cerebri to the central medullary stems, which pass up from the nucleus, through its subdivisions, to terminate in the laminae.

Diagram exhibiting two lobules, with their medullary layers from the primary stem of a lobe entering each lamina: the dotted lines indicate the commissural plates. This view is presented by a vertical section.

The elaborate description of the interior structure of the cerebellum, which Mr. Mayo has translated from the works of Professor Reid, must be well known to all who have given any attention to such inquiries; but though it has been published for more than twenty years, I have been unable to obtain, either from books or personal instruction, any explanation of several points in it which have always appeared to me exceedingly obscure. Indeed, an expression of Mr. Mayo's, "that the inquiry suggests to the mind many more doubts respecting the structure of the cerebellum than it will clear up," seems to go far to prove that even that celebrated and talented in-

vestigator had not completely satisfied his own mind upon the subject. This is further confirmed by the absence of any elucidation which physiology could supply. We see, in his description, that he evidently traces commissural plates, but he gives no such name to them; and if I have comprehended his meaning rightly, the disposition which he points out is entirely at variance with all our received notions of the continuity of nervous fibre from its peripheral extremity to the efferent matter of its centre, whether that be a ganglion or any other collection of grey matter.

In the present attempt to throw some light on this difficult subject, I will

begin by considering Reid's account as translated by Mr. Mayo, and will endeavour, as far as I can, to state the views clearly which he seems to intend to convey: we shall then see what are the difficulties to be met, and shall be better able to judge if the succeeding account from my own dissections will tend to remove them. He commences by stating, "that the three peduncles on either side may be considered as formed by their union with two medullary columns, which are at first directed backward and outward: these enlarge into coarsely fasciculated masses, which contain near the middle of each hemisphere the ciliary bodies. . . the central mass on either side is surrounded on either side by a *laminated stratum*, and in union with the latter constitutes the *medullary nucleus*." This last passage offers great difficulty, and we had better defer the consideration of it until we have examined the various compound parts of the organ. He then says, "the lobes, lobules, and their subdivisions, consist of medullary plates which are arranged one behind the other in succession, and are parallel to the outward furrows; the medullary plates consist of fibres, and tear easily in the direction of them:" this is all easily understood. We then come to a general account of the disposition observed wherever subdivision or branching occurs, as of the stem from the nucleus, or of branches from a stem: and here he interposes a remark to which I would ask especial attention, as seeming to convey his real meaning, viz. "that the parts of the cerebellum are rather contiguous to than continuous with each other." This may, perhaps, be capable of a different construction, but the most evident sense appears to be this—that no direct continuity of fibre exists between the central medullary nucleus and the cineritious cortex of lamina and lobules, the lobules sitting as it were on a saddle upon their ridges. Upon this, if such be his meaning, and it seems further confirmed by Mayo's representation (Tab. VII., fig. 1.) I must venture to dissent, and will endeavour to show by preparations that such is not the case. In describing the "articulation," he says "that they are disposed in lines parallel to the course of the laminae, and consist of a projecting ridge on one surface, and a corresponding furrow on that opposed to it: every lamina is

naturally separable into two equal and lateral portions; at the centre of the base of each lamina is found an angular furrow which receives the ridge of the surface below." This I can quite confirm, but the next paragraph, in which he speaks "of that medullary plate upon which the ridges (more than one) exist for the articulation of the laminae," and "of medullary plates extending from the ridge into the centre of the lamina," has always greatly perplexed me, and it does not correspond with what I think I have observed. In the remainder of his general description he recognizes the external (commissural) plates, skirting accurately the margin of each subdivision, reascending, and lining in succession those that are beyond, and the internal (nuclear) plates passing into the branches from the stems, and so on to the laminae. This exactly accords with what we shall trace. He then proceeds to give a more particular account of each separate part, commencing with the laminae: he describes external (commissural) plates reflected from one to another, and intermediate plates derived from the medulla of the branch itself, which enter each lamina. In the next paragraph (p. 80, Mayo's Commentaries), he most accurately describes the articulations of the lamina, and their superposed medullary layers, and afterwards fully shews how to trace the commissural plates running from one lamina to the next adjoining. He illustrates this description by reference to a preparation such as Mayo has represented (Tab. VIII., fig. 5), where all the *central* medullary plates of a lobe or lobule are removed, and only the external commissural left, so that the various plicæ may be unfolded, and "the arborescent appearance converted into that of an expanded membrane." He then proceeds: "The lobules are articulated by ridges and furrows with the nucleus," and states "that medullary plates enter the central furrows from the ridges which correspond with them:" this, as I before observed, I cannot confirm. Remark upon the structure of the lobes, he says, "that plates composed of medullary fibres are laid in successive layers upon the nucleus;" not, as I conceive, originating from, and continuous with, the nucleus. To confirm this he adduces as an argument, that "there is no relation

between the volume of the hemispheres and that of the medullary columns." But this surely cannot be admitted; for the pons varolii, with its lateral continuations, the crura cerebelli, is well known not to exist in those animals, *as fishes*, which have no hemispheres, but only a median lobe for their cerebellum, and it regularly increases as they become more developed. Now the crura cerebelli are by far the largest of the three peduncles, and consequently have a main share in the formation of the medullary nucleus; so that we cannot consider that no relation exists between the size of the nucleus and its surrounding hemisphere: neither can I agree, on inspection of a vertical section of a hemisphere of the cerebellum, "that the medullary substance of the branches does not diminish in proportion to the minor branches given off from them. These statements, however, seem quite to coincide with the idea, that the parts of the cerebellum are *contiguous*, and not *continuous*."

We now return to the difficulty which presented itself to us at the outset, viz. to consider what is the nature of the structure to which he gives the name of "laminated stratum:" he says it is immediately within the lobes, supporting these processes on the one hand, and on the other it forms the "exterior shade" of the nucleus. Now from these expressions, without reference to anything

else, I could not, I think, form any other conception than such as the annexed diagram conveys, where the dark line with its ridges represents the "laminated stratum" surrounding the central mass.

In a succeeding sentence he observes, "It would seem as if the component fibres run across each intermediate furrow, and meeting form each ridge, and mount together into the lobule:" thus the medullary fibres of the lobule would come from its *own* ridge, as Mayo shows (Tab. VIII., fig. 4,) which, I think, I can prove not to be the case; lastly, he concludes by describing the course which the fibres of these peduncles pursue as they pass through the nucleus.

From this review which I have attempted the reader will perceive that if I have comprehended the learned author's meaning aright, the chief points requiring further elucidation relate to the connection of the nucleus with the lobes and their subdivisions, and might be stated as follows:—

Do the ridges for the lobes, lobules, or laminae, exist for each order of subdivision on any *one* surface, as Mayo shows (Tab. VIII., fig. 7.) or are they placed one behind the other, and on a deeper level, as this diagram would indicate? Again, do medullary plates enter each lamina, lobule, or lobe, from the ridge which corresponds to it, or do they come, as the same diagram shews, from the ridge preceding? These questions I will endeavour to answer in the account which I now proceed to give of the structure of the cerebellum as it appears from my dissections.

ADHESION OF THE PERICARDIUM.

To the Editor of the Medical Gazette.

SIR,

AFTER perusing the second of the Gulstonian Lectures for 1844, by Dr. George Hilario Barlow, published in a late number of your journal, I cannot

refrain from expressing a conviction that, in his mode of delivering and recording a portion of the above discourse, that gentleman has failed in treating me with the courtesy and strict justice which are due from a scientific investigator towards every individual who faithfully labours in the same pursuits.

I beg leave to place before you briefly the grounds upon which I form this opinion.

In the 7th Vol. of the *Guy's Hospital Reports*, (page 421), I published a memoir wherein I sought to prove, and, I believe, succeeded in establishing, the fact, that adhesion of the pericardial surfaces, far from producing hypertrophy and dilatation of the heart (as maintained by Dr. Hope and many other writers upon the subject) has a tendency to be followed by general diminution in the size of that organ and its vessels, and contraction of its cavities; providing there has not also been superadded disease of the valvular passages of the heart, or continued obstruction to the pulmonary or systemic circulation. This argument was stated at considerable length, and supported by reference to cases and preparations. Upon the publication of the number which contained my essay, I was not a little surprised to find that Dr. Barlow (who is the medical editor of the work) had, in a paper "On Certain Diseases originating in Early Youth," inserted a few pages farther on (p. 488), advanced the identical proposition, relative to the pericardium, which I had sought to prove. I must confess that I felt somewhat chagrined at this, as the investigation which led to my conclusion was a long and laborious one, and as I believed that I was the first writer upon the subject who had arrived at the conclusion in question*. Still, as Dr. Barlow merely stated the fact in the form of a single axiom, occupying three or four lines of letterpress, and declined bringing forward confirmatory cases, with the observation that the subject had already been well illustrated by me in the same work, I thought proper to allow the affair to rest in that position. In his second *Gulstonian Lecture*, however, (*GAZETTE*, pp. 755-56), Dr. Barlow has again advanced the views, with regard

to adhesion of the pericardium, to which I have alluded (that lecture being founded upon the above-cited paper, on the Diseases of Early Youth, in the Reports), and has there argued the point at discretion, and cited two cases as confirmatory of the reasoning adduced; and in doing so, he has clearly taken the task of maintaining the fact (as one not commonly recognised) altogether into his own hands, without making the slightest allusion to my researches, or acknowledging the part which I have taken in developing the doctrine which he is desirous to establish.

Now, sir, although I am perfectly well aware that a lecturer or essayist is not always required to mention the authority for every acknowledged principle which he adduces, I cannot but feel that, considering the very peculiar circumstances under which Dr. Barlow first advanced the pathological fact to which I refer, and taking into account the perfect acquaintance he must have had with my writings upon the subject—it having been his office to assist in correcting the proof-sheets of my paper before publication—he was imperatively bound, in delicacy and in justice, whenever he took upon himself the task of proving this question—which is still a novel one, and the proof of which has, I believe, hitherto rested with myself—to acknowledge, in a fair and ingenuous manner, my claims to the establishment of the fact. It is in consequence of Dr. Barlow having neglected to pursue such a line of conduct that I now take the liberty of addressing you.

I beg to state, in conclusion, that I have adopted this course, not from any litigious or vindictive feeling, but from a determination to maintain the justice of my claim to the credit of developing a fact the investigation of which cost me a lengthened period of very arduous application and research.

I am, sir,

Your obedient servant,
NORMAN CHEVERS, M.D.

Upper Stamford Street, March 14, 1844.

* Dr. Copland (in the article *Heart*, Medical Dictionary, Part iii. p. 214) relates a case in which there appeared to be clear evidence that adhesion of the pericardial surfaces had been followed by atrophy of the heart. But the development of the principle under consideration cannot be attributed to that distinguished observer; as it is evident, from several clauses in the above-named article, that he considers adhesion of the pericardium to be one of the states which have a tendency to produce cardiac hypertrophy.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

FEES AND PAYMENTS.

THERE will always be two modes of remuneration in such a profession as ours—by payment, and by a fee or gratuity. Payment will depend directly on demand and supply, and will always bear a pretty accurate proportion to the actual value of the commodity supplied, with a fair profit on the material and outlay. The idea of payment runs through every human transaction whatever. It is invested with no sort of dignity; but, on the contrary, the receipt of payment, hire, or wages, has rather the idea of humiliation attached to it. But, humiliating or not, like certain animal functions which we agree to perform without talking of them, it is quite universal, from the monarch of a free people to the lowest paid servant; it is a part of the right divine of kings, and of the right of the meanest subject. A fair day's wages for a fair day's work, as Mr. Carlyle truly observes, is a law of nature.

An ill bred subaltern who draws his pay with an air of importance, pays away the cheque with a still fiercer aspect to the tradesman who humbly solicits the settlement of his little account; there is no other degradation or elevation in either case than what arises from the bad taste of the parties; and, were both well-bred men, neither would feel any. One of the affectations of the present day, not so harmless as might appear at first sight, is a desire on the part of general practitioners to substitute "small fees" for the old-fashioned medical bill. The real absurdity of a doctor's bill, as we shewed in a former article, is,

that it is a charge made for one thing, to remunerate for another—a charge for drugs instead of for attendance. Remove this inconsistency, and the whole evil vanishes. If the receipt of payment be so serious an evil, let it happen as seldom as may be. Surely the giving a stamped receipt for ten pounds once a year is not a less dignified proceeding than the taking a crown-piece forty times. But this is one more of the absurdities to which a desire for change has given rise amongst the unthinking or discontented, and implies a total misconception of the nature and meaning of a fee.

A fee is supposed to be a gift conferred for a service rendered, without a previous bargain.

Its amount varies according to the estimation in which the giver holds the services or the person of the receiver. The notion of recovering fees by civil action is totally inconsistent with this idea, and is never entertained, that we know of, by lawyers. The recovery of *payment*, on the contrary, for work done or material supplied, is a matter of daily suit. It implies previous contract, tacit or specified.

One great social advantage possessed by our profession has been the remuneration of a large body of its members by fees only. Another advantage, of a different kind, has been, that the bulk of the profession has been able to insist on payment for service performed and materials supplied. This has enabled men to enter practice on terms of compliance with either of the two customs. The fact of payment does not exclude the idea of a fee or gratuity, which may be added according to the given estimation of the services or the person of the receiver; but a fee or gratuity does exclude the idea of payment. Physicians and pure surgeons should therefore be very cautious how they either break the

rule of receiving only fees for their services, which are thereby admitted to be of a special value, or of giving more attendance than the fee for such special service is intended to cover; and general practitioners should be careful not to depreciate the custom of giving fees, nor their customary amount, as such customary amount is an index to the esteem at which professional services are habitually rated by the public. Apothecaries have suffered much damage and degradation, at one end of the scale, by raising drugs in public estimation above their real value; let them take care not to commit a contrary fault, by depreciating the services of the physician, or lowering the amount of fees.

COLLEGE OF PHYSICIANS.

ELECTION OF PRESIDENT.

THE recent elevation of Dr. Paris to the office of President of the College of Physicians, which we announced last week, has brought upon us several inquiries as to the mode of election on these occasions.

It is thus:—There exists in the College of Physicians a body called the "Elects," amounting to seven, and who, in the present instance, consisted of Dr. A. Frampton, Dr. Lambe, Dr. Turner, Dr. Thomas Hume, Dr. Hue, Dr. John Bright, and Dr. Paris.

On the demise or resignation of the President, they, the said elects, choose from among themselves one to fill the vacant chair. None of the other members of the College are either eligible as candidates, or have any thing to do with the election.

COOPER PRIZE.

THE prize established by Sir Astley Cooper, which was this year to be given to the author of the best essay "on the Structure and Uses of the

Thymus Gland," has been awarded to Mr. Simon, of King's College.

This is the first occasion on which Sir Astley's bequest has come into operation. The prize amounts to three hundred pounds.

THE MEDICAL PERIODICALS.

THERE has been, for some time back, a considerable stir among our weekly contemporaries. The circumstance chiefly deserving of attention has been the transition from what is usually understood by a "journal," to the shape and form of a newspaper—the wrapper being abandoned, and the whole printed on one large sheet, so that the advertisements constitute an integral part of the brochure. The ostensible advantage of this is, that by having the sheet stamped it admits of being transmitted by post.

If it be asked what *we* intend to do amid all this commotion, we answer that we are quite alive to all that is passing around us, and are determined to adopt any and every improvement which shall appear calculated to maintain the MEDICAL GAZETTE in the high position and extensive circulation it has so long enjoyed. From this it will be perceived that we have no intention of altering its present form or bearing. At one time, indeed, an edition of the GAZETTE was published in such shape as admitted of its being stamped and transmitted by post; but the facilities of communicating with all parts of the kingdom by railroads, and otherwise, were found to be so great, that scarcely anything was gained as to time by the medium of the post, and the plan was abandoned after a short but sufficient trial.

While, however, we decline to follow the example of our contemporaries, by reducing the GAZETTE from two sheets and a wrapper, to one sheet without

any cover, we beg to state that we have made various arrangements for improving its several departments — more especially by the publication of notes of various lectures, and by extending the departments allotted to analytic and foreign literature ; together with various other changes which will be developed in our forthcoming volumes, and which we trust will prove satisfactory to our readers.

“MEDICAL PROTECTION ASSEMBLY.”

A MEETING, which was numerously attended, was held at the Crown and Anchor, on the evening of Monday, the 25th, on which occasion the chair was taken by Mr. Ansell, and the business principally conducted by Messrs. Carpue, Ayres, Lynch, Wilson, and Wakley.

The chairman stated that a previous meeting had been held on the 20th of January, the objects of which were two-fold ; first, in reference to the charter which had recently been granted to the College of Surgeons, and to the steps which had in consequence been taken by the Council of that body ; and secondly, to consider the intention of the Secretary of State for the Home Department, to introduce a bill for the regulation of the medical profession. At the meeting alluded to an unanimous vote of censure had been passed, in regard to the provisions of the said charter, and a Committee appointed, which had convened the present meeting, to recommend the establishment of a society to be called the Medical Protection Assembly.

The secretary then read the report of the Committee, expressing their disapprobation of the new charter, and more especially denouncing the principle of excluding any class of members from the Council.

He was followed by Mr. Carpue, and several of the gentlemen above named. The principal points of objection urged against the charter were, that practitioners in midwifery were excluded from the Council ; that the election into the governing body was limited to certain irresponsible parties ; and that invidious and unnecessary distinctions were thus introduced among equals.

Mr. Wakley afterwards addressed the meeting, and professed his readiness to forward their objects in any way in his power.

Before the meeting broke up, the chairman stated that the subscriptions amounted to £100, including £25 from the Hon. Member for Finsbury.

SIMPSON'S NEW INSTRUMENT FOR CRUSHING LARGE CALCULI IN THE BLADDER.

Shewn at the Royal Medico-Chirurgical Society, on Tuesday, March 12, 1841.

HAVING been applied to a few weeks back, in a case where the stone was supposed to be too large to extract without first breaking it, and as the instruments that have hitherto been made for the purpose have proved useless, in consequence of the difficulty, or rather impossibility, of opening the blades of the forceps after their introduction into the bladder, so as to grasp and crush the stone, partly from the great thickness of the blades, and partly from their being fixed together ; I have constructed the instrument described in the following lines, from which I consider it will be obvious that, as the blades are introduced separately, and the stone may be comparatively easily crushed, the important and so-long-desired object is at length attained, namely, of being enabled to break up a large stone, and extract it by fragments, without greater danger than that usually attending the ordinary operation of lithotomy.

This instrument, which is for the purpose of crushing calculi that are found to be too large to extract by the ordinary operation of lithotomy, consists of two strong, curved, flattish blades, rather more than three inches in length, which, together with the handles, make the whole length of the instrument

about fourteen inches. The blades are introduced into the bladder separately, so as to get round a large stone more easily. After the stone is seized between the blades, they are locked or connected together by means of a button joint, something similar to that of Rigby's midwifery forceps. After the blades are locked together, a flattish bar, with a male screw cut on the edges, is fixed, by means of a screw, to one side of the forceps, and passed through an opening made for it on the other. On this screw, and outside the handles of the forceps, a washer is first placed, and then the handle with the female screw is put on the bar; and, by turning it on the screw bar, the handles and blades are gradually closed together. Should the stone not be very hard, this power may be sufficient to crush it; but if not, a slide fits into an opening in the screw bar that serves to close the blades. This slide fixes by means of a screw in the centre, according to the width the blades may be opened, and a drill is passed through the hole in the slide (in which a screw is cut for the purpose), and also through a swivel which is fixed at the lower part of the forceps, almost under the joint. A blunt gorget may be passed into the bladder, to guide the drill, and prevent its touching any part of the wound. The handle of the drill is then turned round and round till it arrives at a stop placed on the drill, to prevent its passing beyond the ends of the blades of the forceps and injuring the bladder; thus boring away the centre of the stone, and consequently considerably weakening it. The blades may then be closed by turning the handle on the screw bar, and thus crush the stone to pieces. Should the first hole not weaken the stone sufficiently, the forceps can be opened, and the stone loosed from their grasp, and by moving the stone, and seizing it in a different position, another hole may be bored; but the probability is, that, in most cases, the one hole would be found quite sufficient. The stone having been broken into small pieces, they can then be extracted by the usual forceps or scoop in the ordinary way. The length of the incision in the bladder required to introduce and use these forceps is not more than that usually made for the ordinary operation in the average of lithotomy cases.

There is also another pair of forceps, of about the same length, but with straight blades, and made much stronger, to be used in the same manner as those already described, but so as to enable the operator to crush the stone without having recourse to the drill at all.

RESULTS OF OPERATIONS.

To the Editor of the Medical Gazette.

SIR,

ON looking through the admirable Prize-Essay on the Formation, Constituents, and Extraction of Urinary Calculi, by Dr. Crosse, I noticed a passage which so strikingly bears upon the point insisted on by Mr. Phillips, in his judicious letter of last week, viz., the necessity of taking large numbers of operations in order to get at any thing like a correct rate of mortality, that I cannot resist the temptation to transcribe it for your readers. "Mr. Martineau's short paper on lithotomy, published in the *Medico-Chirurgical Transactions*, and dated January, 1821, contains a list of eighty-four patients operated on successfully, with only two exceptions. It is singular, and worthy to be noticed, that the next two patients publicly operated on by him, at the Norfolk and Norwich Hospital, both died; which is enough to abash the surgeon who should presume upon success according to his experience" (p. 155).

With the two additional fatal cases even, the success of Mr. Martineau, I believe, is unparalleled in the annals of surgery; but how different is the rate of mortality according as we include the 85th and 86th cases, or not. Including them, the deaths would be 1 in $21\frac{1}{2}$; not reckoning them, 1 in $21\frac{1}{2}$. So that it is clearly desirable, in statistical calculations, to have recourse to as large numbers as possible.

In prevalent severe epidemic diseases I have frequently noticed the desirableness of this. Several deaths may have occurred in rapid succession early in the epidemic period, so as to lead one to infer, without recourse to larger numbers, that the rate of mortality was high; but many severe cases may subsequently have occurred where the patients struggled through to recovery, the rate of mortality being thereby considerably reduced, and *vice versa*.

The statistics of the medical profession are now claiming more general notice than they have hitherto done, and great utility is likely to be the result. By the by, as not entirely irrelevant to the subject of this note, can you inform your country readers if the Statistical Society has any connection with members of the medical profession: if there be a medical department of that Society? If so, it would be well for medical practitioners generally to be directed to a series of concise observations for statistical purposes. These could be made with little or no labour, and I for one should be most happy to take charge of any printed papers for being filled up, and adapted to subjects

within the range of general practice, which might be prepared by the Society.

I am, sir,

Your obedient servant,

T. H. B.

Bedford, March 20, 1844.

DOES DALBY'S CARMINATIVE CONTAIN OPIUM?

To the Editor of the Medical Gazette.

SIR,

THE last number of the *MEDICAL GAZETTE* contains a paper by Dr. John B. Beck, copied from the *New York Journal of Medicine*, "On the Effects of Opium on the Infant Subject." In this communication the author condemns the use of Dalby's Carminative as dangerous, from containing opium, and he quotes the opinion of Dr. John Clarke and others to the same effect. Now, in Dr. Paris's *Pharmacologia*, the following formula is given as the composition of Dalby's Carminative:—

Carbonate of Magnesia ℥ij.

Oil of Peppermint ℥j.

— Nutmeg ℥ij.

— Anise-seed ℥ij.

Tincture of Castor ℥xxx.

— Assafoetida ℥xv.

Spirit of Pennyroyal ℥xv.

Compound Tincture of Cardamoms ℥xxx.

Peppermint Water fl̄ij.

I have never prescribed the nostrum sold as Dalby's Carminative, and of course cannot say any thing in its defence against the sentence of condemnation pronounced against it, as containing opium.

The experience of a series of years, however, enables me to recommend the composition above quoted from Dr. Paris's work, as a valuable and useful carminative for the griping and flatulence so frequently troublesome to infants in the first months after birth. Instead, however, of giving 30 or 40 drops, a dose which Dr. Beck mentions as being known to have proved fatal, I give from 3 to 5 minims only for a dose. In this proportion, combined with one grain of carbonate of magnesia, and the one-sixth or one quarter of a grain of rhubarb, and sweetened with syrup, it forms a pleasant carminative, an acid and aperient mixture, and may be given with safety and advantage. In some instances, where diarrhoea prevails, from two to five minims of Tinctura Camphoræ Composita may be advantageously combined with it, whether with or without the rhubarb and magnesia.

In conjunction with the cases of the dangerous powers of opiates and stimulants in young children, I may take the opportu-

nity of mentioning the case of a little girl, two years of age, who fell suddenly into a heavy, almost apoplectic stupor, accompanied with vomiting, from the smell of Eau de Cologne, a bottle of which had been spilt by accident on the child's clothes. If you think this communication worthy a place in the *MEDICAL GAZETTE*, your insertion of it will oblige your constant reader,—J. A.

March 13, 1844.

NEW TERMS IN ANATOMY.

To the Editor of the Medical Gazette.

SIR,

THE difficulties of anatomy are so much increased by the confused state of its nomenclature, and the practice of inventing new words has grown to such a height, that I am anxious to protest, through the medium of your columns, against the introduction of a fresh batch of novelties with which we are threatened in a recent publication.

In the translation of Wagner's *Physiology*, which has just appeared, it is proposed to call the three grand divisions of the brain—*pro-cerebrum*, *meso-cerebrum*, and *post-cerebrum*. On referring to the German original, I find that these barbarous words are not used by Professor Wagner: they have been coined by his translator, as equivalent to "*vorderhirn*," "*mittelhirn*," and "*hinterhirn*."

Fore-brain, *middle-brain*, and *hinder-brain*, is the plain English of these words; but Dr. Willis seems to be fond of Latin and Greek, and so makes his compounds by mixing up those languages in nearly equal proportions.

I trust, sir, you will interpose in behalf of us students, whose progress is already so grievously impeded by technical difficulties, and entreat all writers, whether of original works or of translations, to make use as much as possible of well-known and familiar expressions, and, if *new words* must be invented to describe *new things*, at least let some regard be paid to the structure of the languages employed.

If the different portions of the brain are to be arranged according to a Greek nomenclature, *pro-encephalon*, *mesencephalon*, and *metencephalon* might be tolerated; or if Latin be preferred, *præ medio*, and *post-cerebrum*; but no rational defence can be made for Dr. Willis's words, which set all etymology at defiance, and are only fit to be classed with the "*Patent Paravent*," or Mr. Cabburn's "*Anti-doloric oil*."

I am, sir,

Your obedient servant,

A LONDON STUDENT.

March 21st, 1844.

ON THE
INFLUENCE OF OPIUM UPON THE
CATAMENIAL FUNCTIONS.

By JAMES McCUNE SMITH, M.D.
Of New York.

PEREIRA observes, "that we have little positive information as to the effects of opium on the reproductive organs of women. It is said that the catamenia, lochia, and secretions of milk, are unaffected by it;" whence he infers "that its use in the female is not likely to be attended with retention of the uterine or mammary functions."

The following cases, which have fallen under my notice within the last four years, give uniform evidence contrary to the above view.

CASE I. E. L.—d, a middle-sized, plethoric young woman, æt. 24. In 1837, having procured an abortion by means of some powerful drug, she sent for a physician, who gave opiates in the course of his subsequent treatment. From that time until April 1843, she resorted daily to laudanum, and gradually increased the dose to four ounces per diem. Her appearance last April was as follows: look, stupid; complexion, florid; person, fat; bowels, regular; and she ate very little food. Her catamenia, which had been regular until January, 1837, have never appeared since. I believe she is now in the Magdalen Asylum at Yorkville.

CASE II. E. M.—l, æt. 23, of middle size and sanguine temperament. About three and a half years ago, during an attack of acute rheumatism, laudanum was freely administered to her. During her recovery, and until March, 1843, she continued the daily use of the tincture of opium; and from 1841 to 1843 she drank from four to six ounces per day. In March last, she had clear complexion, ruddy cheeks, good general health, bowels regular, and ate little food; but from the date of her rheumatism, until March, 1843, her catamenia did not appear, notwithstanding she had been perfectly "regular" until that attack. She went into the country in April, 1843, where she could not obtain any laudanum; but she applied to a physician, who prescribed an emmenagogue, which was followed, at first, by a slight, and subsequently, by several profuse, but regular, returns of the catamenia. She has recently (July 20th) returned to this city, and has resumed a very moderate allowance of laudanum.

CASE III. S. S.—h, a short, fleshy, plethoric young woman (coloured), æt. 26. Until July, 1837, she had menstruated regularly; but, at that date, she commenced the daily use of laudanum, to allay the pain of *onychia maligna* of the great toe of the

left foot. She continued drinking from two to four ounces of tr. opii, per diem, until June, 1842. During these five years, although her general health remained unimpaired, her catamenia did not appear. At the last-named date she was cured of the *onychia* by an operation. The succeeding month, and every month since, the menses have punctually appeared, without the aid of any medicine.

CASE IV. R—n, æt. 25, of middle height, robust, sanguine temperament: has a child four years old. About two years ago, while confined to her room by a fracture of the left tibia, she commenced using opium to relieve pain and restlessness. She has sometimes used twenty or thirty grains of opium per day, for two or three months steadily; at other times, she quitted the stimulant entirely, for the same length of time. While she continued using the opium daily, her catamenia did not appear; but, on forsaking the drug for a month or two, she becomes "regular" without an emmenagogue. Her general health is good, and she has not been constipated at any time.

CASE V. E. R—, æt. 18, a young, unmarried female (coloured), applied to me, in May or June, 1841, for relief from an increase of the quantity and frequency of the catamenia. She was pale, thin, and of the *nervo-sanguine* temperament. Pulse frequent, but soft; head dizzy. She has a sister and brother; both are married and have progeny. There were no coagula in her uterine discharges, and except physical weakness, her general health was good. Having tried the ordinary treatment without success, I gave her a combination of acetate of lead, camphor, and *opium*, in minute, frequently repeated, doses. I commenced the use of this combination on the fourth day of the persistence of the discharge, and continued the remedy until the discharge ceased. She was greatly relieved by this practice. Shortly afterwards, on leaving the city, she procured a copy of the prescription; and, without my knowledge, continued using the pills (as her sister informed me lately) nearly a year. The catamenia gradually diminished, and, at the end of a year, entirely ceased. She was subsequently (Sept. 1842) married. Her general health remains good, her person is thin; but menstruation has not recurred, nor has she yet become pregnant. Since abstaining from the pills (Aug. 1842), she has repeatedly resorted to emmenagogues, prescribed by various physicians, but without success.

Remarks.—The first four of the above females are courtezans. But their vocation cannot have been the cause of the arrest of their menses; for I can say, from a somewhat extensive experience in the Lock Hospital at Glasgow, that this unfortunate class

have no peculiar liability to suppressio mensium. E. M.—I (Case II.) informed me that she was acquainted with several opium-eaters, in all of whom the menses have been arrested, as they believe, by opium.

Without assuming from so few cases that the daily use of opium will *always* arrest the catamenia, I submit them, in the hope that they may attract the attention of medical men to whatever facts may be within their reach. It will be interesting to ascertain, in relation to married women, who have borne children previous to a resort to opium-eating, whether this habit arrests their catamenia, and their capacity for conception; or, whether it arrests the one and not the other. It may also be worth the inquiry, whether opium, in skillfully regulated doses, may not be used as a means to bear women safely through the critical disturbances which occur at the "change of life."

One circumstance is common to all the above narrated cases, viz., the arrest of the catamenia was not followed by the vital disturbances which attend suppression from other causes; or, in general terms, opium, in daily doses, arrested uterine periodicity without disturbing other ordinary vital functions. Here we have an analogy with other well-known effects of opium; for this drug, to a great degree, arrests hunger, which, in the present state of civilized society, is a *periodic habit*, for it is seldom allowed to become an actual *want*. In a therapeutical point of view, opium exerts an almost uniform influence as an arrester of periodicity. As a narcotic, its influence is not uniform, for it does not always produce sleep; and I am inclined to the belief, that when sleep does follow its exhibition, it is rather a consequence of the absence of (an arrested paroxysm, than of a direct narcotic influence.—*New-York Journal of Medicine*.

EFFECTS OF A LARGE DOSE OF ARSENIC TAKEN BY A LUNATIC.

By A. B. SHIPMAN, M.D. Cortlandville, N.Y.

IN the year 1838, a gentleman who had been insane two or three years, the cause of which was probably ill health from disorder of the digestive organs, acting upon a nervous temperament, took a teaspoonful of the white oxide of arsenic with a view of destroying himself. It was taken immediately after eating a hearty dinner, and washed down with a draught of water. Soon after, or within half an hour, he vomited freely, and in the course of the day a diarrhoea set in,

which followed him a day or two. He then informed his medical attendant of what he had taken, and his regret and contrition at the act. All this time he experienced but little of what could be attributed to the poison; the diarrhoea was not attended with any thing peculiar, he had eaten his usual meals with a tolerable relish, and complained of no unusual burning or pain in the stomach and bowels. Within a week or so he was taken with severe pain in his legs and arms, which he described as most excruciating; the sensation he compared to the gnawing of rats, or the boring of a gimlet into the bones: there was some swelling of the legs and feet, but no preternatural heat. After the pain had continued some days, a partial paralysis of the limbs was observed. He took various medicines, mostly of the anodyne class, with stimulating liniments and frictions, which were persevered in for a length of time. The paralysis, however, remained obstinate for months. The strychnine was finally given, and continued several weeks. The paralysis gradually left him, and he regained his health, and resumed his business as a merchant. But what was most curious to the physician, and to the patient of the most importance, was the complete restoration of his reason, and ultimately his health. Previous to his insanity he was of a reserved and cautious disposition,—was taciturn, diffident, and exemplary in his conduct,—was on the point of contracting an eligible engagement,—his pecuniary circumstances were unembarrassed. Yet all at once he became talkative, boisterous, and mirthful. Entered into speculations, contracted for farms and property which he did not want, supposed himself in possession of immense sums of money, and that his speculations would conduct him to boundless wealth. He insisted upon his marriage immediately—invited every body he saw to attend his wedding. His marriage finally took place, as his friends imagined it might be a means of restoring him, or an exasperation of his malady a result of his wishes being thwarted. But these palmy days of ideal wealth and splendour soon wore away, and he sank under a gloomy, desponding, and dejected lunatic, unfit for business or society. He was however harmless, and lived with his wife for two or three years, attending to no business. He was in this state when he took what he imagined would be his last dose, but which in all probability was the means of restoring him to reason. Since that period, there has been no signs of insanity, and his health has been good since the removal of the paralysis from his limbs. He has resumed his business as a merchant, and conducts it judiciously and with success.—*American Journal of the Medical Sciences*.

ON THE THREE IMAGES REFLECTED IN THE EYE.

M. MAGNE lately addressed a note to the Academy of Sciences, relative to the three images reflected in the eye by the light of a taper.

The late Professor Sanson began to observe in 1836, and pointed out to his clinical class in 1837, that when a candle is placed before the eye of an amaurotic patient, whose pupil is dilated, three images of the flame can always be distinguished succeeding one another from before backwards. The first, or anterior one, which is the brightest, is erect; the second, or middle one, which is less bright, is reversed; and the third, or posterior one, is much fainter than the other two, and is erect, like the first one. M. Sanson and his pupils arrived at the same results, and ascertained that the anterior erect image is produced by the cornea; that the middle reversed one is owing to the posterior segment of the crystalline capsule; while the posterior erect image arises from the anterior segment of the same capsule. Opacity of the cornea destroys all three images. Opacity of the anterior capsule destroys the two posterior images. Opacity of the posterior capsule prevents the production of the reversed image.

In other words, when there is a posterior capsular cataract, we cannot see the middle or reversed image; in anterior capsular cataract, the anterior erect image is alone visible; and so it is in capsulo-lenticular cataract. The experiments of M. Pasquet, combined with these, have confirmed the conclusion that a cataract, even at its commencement, can always be distinguished from amaurosis and glaucoma. For since in glaucoma and amaurosis the alteration does not affect the crystalline apparatus, the three images of the flame still remain.—*Gazette Médicale*, Jan 27, 1844.

MEDICAL RELIEF FOR THE POOR.

A SELECT Committee of the House of Commons for inquiring into the present system of administering medical relief to the poor, under the Poor-Law Amendment Act, is now sitting. They have imperatively prohibited the publication of any thing that passes until their report shall have been presented.

EFFECTS OF DRAINAGE ON HUMAN LIFE.

THE Rev. Professor Buckland, at a public meeting held in Oxford last week, said that,

in the parish of St. Margaret, Leicester, containing 22,000 inhabitants, it appeared that one portion of it was effectually drained, some parts but partially so, and others not at all. In the latter the average duration of life is thirteen years and a half, while in the same parish, where the drainage is only partial, the average is twenty-two years and a half, thereby shewing the frightful effects of a bad atmosphere.—*Times*.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, March 21, 1844.

J. P. F. P. Hains, Dartmouth.—S. S. Smith, Munslow's Aston, Shropshire.—P. Grubb, Plymouth.—J. B. Leeson, Leicester.

A TABLE OF MORTALITY FOR THE METROPOLIS,

Shewing the number of deaths from all causes registered in the week ending Saturday, March 16, 1844.

Dropsy, Cancer, and other Diseases of Uncertain Seat.....	82
Diseases of the Brain, Nerves, and Senses..	175
Diseases of the Lungs and other Organs of Respiration	307
Diseases of the Heart and Blood-vessels ...	30
Diseases of the Stomach, Liver, and other Organs of Digestion	66
Diseases of the Kidneys, &c.....	12
Childbed	9
Paramenia.....	0
Ovarian Dropsy	3
Disease of Uterus, &c.	6
Arthritis.....	0
Rheumatism	0
Diseases of Joints, &c.	3
Carbuncle	0
Phlegmon	0
Ulcer	2
Fistula	1
Diseases of Skin, &c.....	0
Old Age or Natural Decay.....	82
Deaths by Violence, Privation, or Intemperance	32
Small Pox	21
Measles	21
Scarlatina	43
Whooping Cough	32
Croup	9
Thrush	4
Diarrhoea	3
Dysentery	3
Cholera	0
Influenza	3
Ague	2
Remittent Fever	0
Typhus	28
Erysipelas	6
Syphilis	2
Hydrophobia.....	0
Causes not specified	2

Deaths from all Causes.....1030

WILSON & GOOLVY, 57, Skinner Street, London.

INDEX TO VOL. XXXIII.

(VOL. I. FOR THE SESSION 1843-44.)

A.

- ABDOMEN, Dr. A. R. Brown's case of tumor of the, 692.
- Aberle's, Dr. mode of extracting calculi from the bladder, 752.
- Abscess, Dr. Perkins's case of, through the lumbar region of the back, 431.
- Abscess and fistula connected with the rectum, Sir B. Brodie's lectures on, 515, 554, 584.
- Accidents, statistical account of the, brought to the London Hospital during the year 1843, 751.
- Acid, pyroligneous, Dr. Furnivall on the employment of, in tinea capitis, 16.
- Acne indurata, inquiry as to the best treatment of, 671.
- Acne indurata, creosote recommended for the cure of, 704.
- Acquisitions to natural history, 590.
- Adulteration of blue pill, 523.
- Advice, judicial, to medical practitioners, 672.
- Albuminuria, Mr. G. Robinson on, 154.
- Albuminous liquids, Dr. Percy's analysis of, 610.
- Aldis, Dr. J. C. B. caution by, to medical students, 220.
- Allnatt, Dr. on seminal discharges from the urethra, and on the influence of creosote in mucous and sanguineous discharges from the urethra, 18.
- Allnatt, Dr. on a case of spasm of the glottis, 273.
- Amaurosis, Dr. Felsch on a case of, following retrocession of itch, 221.
- Ammonia croto, 491.
- Amputation of the shoulder-joint, Mr. B. B. Cooper's case of alarming syncope from the admission of air into a vein during, 376.
- Amputations, Mr. B. Phillips on the results of, 803.
- Anatomy and physiology, Dr. Knox's contributions to:—Memoir on the cervical ribs in man, 156; supplementary observations on the preceding memoir, describing more minutely the anatomical preparations illustrating the anatomy of the cervical ribs, 166, 210.
- On hermaphroditism, a memoir read to the Royal Society of Edinburgh, in 1827 and 1828, 241, 277, 293, 417, 472, 510.
- The corpus luteum, 367, 573, 605, 716, 759.
- On the anatomy of the inguinal canal, 536.
- Anatomy and physiology, extracts from Mr. Paget's report on the progress of, during 1842-3, 636.
- Anatomy, difficulties occasioned to the student by the employment of new terms in, 677.
- Anatomical manipulation, Messrs. Tulk and Henfrey's recent work on, reviewed, 803.
- Aneurism of the aorta, Dr. O'Bryen on the diagnosis of, 189.
- Apothecaries' Hall, list of gentlemen who have received certificates, 52, 64, 96, 128, 160, 192, 256, 283, 320, 352, 384, 464, 523, 560, 640, 672, 704, 752, 784, 816, 848, 800.
- Army surgeons, Mr. Calder on the education of, 270.
- Army surgeons, remarks on the education of, by an assistant-surgeon, 546.
- Arsenic, Professor Reinsch on a new mode for the detection of, 31.

- Arsenic in inveterate syphilis, 224.
 Arsenic, Dr. Shipman's account of the effects of a large dose of, taken by a lunatic, 377.
 Asmus's, Dr. remedy for hydrophobia, 62.
 Astley Cooper prize, 374.

B.

- Babington, Mr. notice of the resignation by, of the office of surgeon to St. George's Hospital, 238.
 Barcq's, Dr. extemporaneous vesicant, 752.
 Barker's, Dr. clinical lectures delivered at St. Thomas's Hospital:—Case of pneumothorax, 161.
 Case of hepatization of the lung, 289.
 On cases of chlorosis, 353.
 Barlow, Dr. on diseases arising from the defective expansion of the lungs in early youth, being the Gulstonian lectures for the year 1843, 705, 753, 785.
 Bath waters, Dr. A. B. Granville on the efficacy of the, 325.
 Beberine, Dr. MacLagan on the properties of, 190.
 Beck, Dr. J. B. on the effects of opium on the infant subject, 767.
 Belgian medical institutions, Mr. Edwin Lee on, 42.
 Mr. Edwin Lee's account of the same, 145, 172.
 Bell, Sir Charles, compliment to the memory of, 61.
 Bell, Mr. Joseph, on the neglect of the sick poor in Scotland, 730.
 Bell's, Dr. account of the epidemic which prevailed at Teheran in the year 1842, 214.
 Belladonna, on the employment of, in the treatment of phimosia and paraphimosia, 32.
 Betts, Mr. G. on the ill effects arising from the circulation of certain particles in the blood, 312.
 Bichromate of potash, Mr. Wilson's case of poisoning by, 731.
 Bigelow's, Dr. case of strangulated intestines, from rotation of the sigmoid flexures, 430.
 Bird's, Dr. Frederic, cases of the successful removal of diseased ovaria, 409, 832.
 Bird's, Dr. Golding, remarks on fatty urine, 110.
 Bird's, Dr. Golding, remarks on the respective value of the different tests proposed for the detection of a diabetic state of the urine, 245.
 Bird's, Dr. Golding, account of Professor Mulder's researches on the existence of oxides of protein in the blood, 615.
 Bird's, Dr. Golding, elements of natural philosophy, reviewed, 419.
 Bischoff, M. on the first formation of the Graafian vesicle, 159.
 Blood, M. G. Betts on the ill effects arising from the circulation of certain foreign particles in the, 312.
 Blood, Dr. Golding Bird's account of Professor Mulder's researches on the existence of the oxides of protein in the, 615.
 Blood, diabetic, Dr. H. Bence Jones on the sugar in, 180.
 Bloxam's, Mr. W. case of ulceration of the internal jugular vein, communicating with an abscess, 176.
 Blue pill, adulteration of, 523.
 Boettger, M. on the best method of removing the stain produced by chemical marking-ink from linen textures, 591.
 Books, analyses and notices of:—
 Dr. John Hastings on pulmonary consumption, successfully treated by naphtha, 19.
 Dr. Watson's lectures on the principles and practice of physic, 21.
 Dr. Little on ankylosis or stiff-joint, 21.
 Mr. Erasmus Wilson on the diagnosis, pathology, and diseases of the skin, 83.
 The prescriber's pharmacopœia, 88.
 Dr. George Gregory's lectures on the eruptive fevers, 114.
 Medico-chirurgical transactions, second series, vol. viii. 151, 176, 214.
 Dr. Granville, the Spas revisited, 181.
 Mr. Walker's oculist's vade-mecum, 420.
 Mr. Pettigrew on superstitions connected with the history and practice of medicine and surgery, 421.
 Dr. Copland's dictionary of practical medicine, part 9, 420.
 Mr. Travers on the physiology of inflammation, 452.
 M. Schlegel's essay on the physiognomy of serpents, by Dr. Trail, 454.
 Mr. Walker's chart of the diseases of the skin, 455.
 Dr. Weekes, the warm-water remedy, 455.
 Dr. John Scott on cataract, and its treatment, 458.
 Dr. Lever's practical treatise on organic disease of the uterus, 551.
 Medical student's guide and almanac for 1844, 578.
 The medical almanac, 578.
 Dr. Hunt on the nature and treatment of tic douloureux, 622.
 Posthumous extracts from the veterinary records of the late John Field, 624.
 Dr. Williams's principles of medicine, 657.
 Dr. Cormack on the natural history, pathology, and treatment of the epidemic fever at present prevailing in Edinburgh, and other large towns, 740.
 Dr. Guy's principles of forensic medicine, 773.

- Messrs. Tulk and Henfrey's anatomical manipulation, 808.
- C.**
- Bostock, Dr. John, on the effect of water drinking in the cure of gout, 693.
- Bowen's, Dr. case of rupture of the uterus in a woman who had twice undergone the Cæsarean operation, 491.
- Bowstead's, Mr. account of the treatment of a case in which an artillery-man was blown from a gun, 339.
- Breast, scirrhus of, in the female, Sir B. Brodie on cases in which it is expedient to perform the operation for the removal of, 623, 664.
- Bridgewater Union, remarks on a late inquest in the, 746.
- Bright's disease, Dr. Percy's account of a case of, with analysis of the urine, 730.
- British Dispensary in Syria, Dr. Holt Yates's clinical report of the, 565.
- Brodie's, Sir Benjamin, introductory discourse on the duties and conduct of medical students and practitioners, 97.
- Brodie's, Sir Benjamin, account of a case in which a foreign body was lodged in the right bronchus, 215.
- Brodie's, Sir Benjamin, lectures at St. George's Hospital:—Abscess and fistula connected with the rectum, 515, 554, 584; on the cases in which it is expedient to perform the operation for the removal of scirrhus tumor of the female breast, 623, 664; on the administration of mercury in syphilis, 665.
- Brodie, Sir Benjamin, note from, in refutation of a statement at the Crown and Anchor meeting to oppose the new charter to the College of Surgeons, 584.
- Brodie medal, 592.
- Bronchitis, acute, Mr. A. G. Proctor on a case of, 213; correction of an error in the report of the case, 318.
- Brown, Mr. on the treatment of gonorrhœa, 16.
- Brown's, Dr. A. R. case of tumor of the abdomen, 692.
- Budd's, Dr. George, Galstonian lectures delivered at the Royal College of Physicians in 1843, see "Galstonian lectures."
- Budge, M. on the extirpation of the salivary glands in animals, 61.
- Burnett, Miss, on the importance of the date-tree, 559.
- Burns, Mr. Peppercombe on the treatment of, 773.
- Burrows, Dr. George, case of carcinoma of the lungs, 697.
- Burton, Dr. H. on the statistics of fever in St. Thomas's Hospital, with reference to treatment, 204, 503, 599.
- Cæsarean operation, case of, successfully performed by Dr. Ziel, at Nuremberg, 783.
- Calculi, Dr. Jones's remarks on the collection of, in St. George's Hospital, 155.
- Calculi of the bladder, Dr. Aberle's mode of extracting, 752.
- Calculi, account of a new instrument for crushing, 875.
- Calculus, bronchial, Dr. Tice's case of, with observations on diseases of the bronchial glands, 153.
- Calculus, large biliary, voided from the rectum, Dr. J. A. Wilson's account of a, 155.
- Calculus, remarkable case of, by M. Segalas, 319.
- Calculus, Mr. Macpherson's case of, removed from beneath the prepuce, 403.
- Calder, Mr. on the education of army surgeons, 270.
- Calomel, Dr. Laner on the local application of, in ophthalmia plenorrhœa, 591.
- Camplin, Mr. on removal of ovarian tumors, in a letter in reply to Dr. Frederic Bird, 29.
- Cancrum oris, Mr. Dunn on a case of, 52, 57.
- Cancrum oris, Dr. Hunt's remarks on, 176.
- Carcinoma of the thyroid gland, Mr. Cæsar Hawkins's cases of, 345.
- Carcinoma of the lungs, Dr. George Burrows on a case of, 697.
- Cataract, lenticular, Dr. W. Mackenzie on a case of, treated by extraction, with remarks on needle-knives, 26.
- Cerebellum, Dr. C. H. Jones on the structure of the, 866.
- Chalk, Mr. W. O. on the effects of the cod's liver oil upon strumous and other diseases, 441, 441.
- Charlton and Williams, Messrs. on a case of extra uterine foætation, 654.
- Charter, copy of the, lately granted to the College of Surgeons, 91.
- Chatto, Mr. John, on the College of Surgeons' charter, 634.
- Chevers, Dr. on adhesion of the pericardium, 871.
- Childbirth, the Registrar-General's Report on the number of deaths from, during four years, 717.
- Chlorosis, clinical remarks by Dr. Barker on cases of, 353.
- Cholera, Mr. Rankin on, 215.
- Cholera, Dr. C. W. Rankin on the treatment of, 831.
- Christie's, Mr. John, case of pneumonia complicated with pleuritis, 335.
- Christison, Dr., on poisoning with laburnum, 105.

- Circulation, interrupted, Sir A. Crichton on, 280.
- Circulation of the embryo of a fowl, the method to be adopted for observing the, 750.
- Clayton's, Mr. Oscar, account of an hysterical affection of the vocal apparatus, with several cases, 177.
- Cleddinning, Dr., on the medicinal properties of the *cannabis sativa* of India, 180.
- Climate of France, M. Fuster on changes in the, 700.
- Cochineal, on the employment of, in the treatment of hooping-cough, 560.
- Cod's liver oil, Mr. W. O. Chalk on the effects of, upon strumous and other diseases, 414, 441.
- Collegiate system, editorial observations on the, 744.
- College of Surgeons, copy of the charter lately granted to the, 91.
- College of Surgeons of England, chronological schedule of the Fellows of the, 376.
- College of Surgeons, editorial observations on the new charter of the, 426, 456.
- College of Surgeons, note from Mr. Guthrie on the fellowship of the, 460.
- College of Surgeons, opinions of the British and Foreign Review respecting the new charter of the, 483.
- College of Surgeons' charter, meeting at the Crown and Anchor to oppose the, 583.
- College of Surgeons' charter, Mr. John Chatto on the, 634.
- College of Surgeons, letters from a "Twenty-eight years' Member" on the recent election of Fellows, 558, 656; from "One of the Fellows," 656.
- College of Surgeons, remarks on the recent election of Fellows, by a Bengal Medical Officer, 750.
- College of Surgeons, lists of gentlemen admitted members, 64, 96, 160, 256, 320, 432, 464, 592, 640, 752, 848.
- College of Physicians, statistics of the, 342.
- College of Physicians, remarks by a "Rural Physician," on the injustice done to country licentiates, 490.
- College of Physicians, Dr. Paris elected president of the, in the room of Sir H. Hallford, 814; additional notice, 874.
- Colles, the late Dr. Abraham, notice of the decease of, with some account of his life, 382.
- Conical cornea, Mr. Middlemore on, 541; Dr. Pickford on, 690.
- Constitutional irritation, or general disturbance, Mr. T. W. King on:—Introductory considerations, 262; definition, *ib.*; a plan of the relation of the animal functions, 263; humoral agencies, and their advocates, *ib.*; varieties of assimilation, 265; plan, 266; influence of generative functions, 267; of exercise, 268; of the capillaries, *ib.*; of the arteries, 269.
- Contagion of plague, on the destruction of the, 496.
- Cooper, Mr. B. R. on a case of alarming syncope from the admission of air into a vein during an amputation of the shoulder-joint, 376.
- Cooper's, Mr. B. B. case of extirpation of an ovarian cyst, 521.
- Copland's, Dr. Dictionary of practical medicine, part 9, notice of, 420.
- Copper, M. Rossignon on the existence of, in organic tissues, 287.
- Cormack, Dr. on the natural history, &c. of the epidemic fever at present prevalent in Edinburgh, reviewed, 740.
- Cornea, Mr. Paterson on the efficacy of prussic acid in opacity of the, 807.
- Coroners' inquests, editorial remarks on two, lately held, 25.
- Corpus luteum, Dr. Knox's memoir on the, 67, 573, 605, 716, 759.
- Corpus luteum, Dr. Knox's contributions to the anatomy and physiology of the, 367, 573, 605, 716, 759.
- Corpus luteum, Mr. Wharton Jones on the, 460.
- Corrosive sublimate, Dr. Frampton on a test for, 78.
- Creosote, Dr. Allnatt on the employment of, in mucous and sanguineous discharges from the urethra, 19.
- Creosote recommended in the treatment of acne indurata, 704.
- Creosote in the vomiting of pregnancy, 784.
- Crichton, Sir A. on interrupted circulation, 280.
- Croup, M. Scoutetten's case of tracheotomy in the last stage of, 750.

 Nerves of the uterus, Mr. Grainger on the, 341.
 Neucourt, M. on the state of the heart in the old, collected from cases at the Salpêtrière, 702.
 Neuralgia of the ureter, case of, 590.
 North Dublin Union House, account of the, 559.

O.

O'Brien, Dr. on the diagnosis of aneurism of the aorta, 189.
 Opening session, editorial remarks on the prospects of the, and advice to students at the commencement of their studies, 21.
 Operations, Mr. J. P. Halton on the average number of deaths in, 390.
 Operations, results of, reply from the surgeons of the Liverpool Northern Hospital, to a paper by Mr. J. P. Halton, 645.
 Operations, on the results of, 876.
 Ophthalmia, M. Velpeau on the circumstances which should regulate the various modes of employing the nitrate of silver in, 63.
 Ophthalmia, pustular, Mr. Leigh on, 371.
 Opium, Mr. Walker on the good effects of, in strangulated hernia, 484.
 Opium, Dr. J. B. Beck on the effects of, on the infant subject, 767.
 Opium, Dr. J. M. Smith on the influence of, upon the catamenial functions, 878.
 Otley, Mr. Drewry, on the presence of cysticercæ in the brain, 346.
 Ovaria, dropsical, Mr. D. H. Walsh's cases

of, removed by the large abdominal section, 47, 686, 723.
 Ovaria, diseased, Dr. Frederic Bird's cases of the successful removal of, 409, 832.
 Ovarium, dropsical, Mr. Southam's case of removal of a, 198, 236.
 Ovarium, diseased, Mr. Greenhow's case of removal of a, terminating fatally on the seventh day after the operation, 521.
 Ovarian cyst, Mr. B. B. Cooper's case of extirpation of, 521.
 Ovarian tumors, Dr. William Hunter's opinion on the removal of, 569.
 Ovarian operations, 383.
 Ovary, the human, Dr. Ritchie's contributions to the physiology of the, 362, 652, 737, 793, 854.
 Ovum, human, Purkinje on the first formation of the, 159.

P.

Paget's, Mr. James, report on the progress of anatomy and physiology, during 1842-43, 636.
 Paralysis, Dr. Webster's case of, without loss of sensation, from disease of the cervical medulla, 151.
 Paralysis, Mr. Hovell's cases of, 481.
 Parrish's, Dr. case of epilepsy induced by a blow on the head, successfully treated, 379.
 Paterson, Mr. on the efficacy of prussic acid in opacity of the cornea, 807.
 Pathology, Dr. John Percy's contributions to, 571, 610, 730.
 Peppercorne, Mr. on the treatment of burns, 773.
 Percy's, Dr. John, contributions to pathology, 571, 610, 730.
 Pericardium, Dr. Chevers on adhesion of the, 871.
 Peritonitis, acute, Dr. Wainwright's case of, 148.
 Peritonitis, Dr. Mayo's record of cases of, treated at the St. Marylebone Infirmary, 540.
 Perkins's, Dr. case of abscess through the lumbar region of the back, 431.
 Pettigrew, Mr. on superstitions connected with the history and practice of medicine and surgery, 421.
 Pharmaceutical Society, regulations adopted and confirmed by the council, for the examination and registration of members, associates, and apprentices, 462.
 Pharmacy, the establishment of a school of, vindicated, 30.
 Phillips's, Mr. Benjamin, clinical remarks on cases treated in the St. Marylebone Infirmary:—Injury of the head, 130; secondary syphilitic affections of the skin, 123; on stricture of the urethra, with its treatment, 257; on the consequences of

- stricture of the urethra, 321; on hip-joint disease, 335.
- Phillips, Mr. Benjamin, elected assistant-surgeon to the Westminster Hospital, 375.
- Phillips, Mr. Benjamin, on the results of amputations, 303.
- Phlegmasia dolens, Dr. Mayo's account of a case of, 581.
- Phthisis, Dr. J. W. Griffith on the process adopted by nature for the cure of, 691.
- Phthisis, atrophy of the heart in, 222.
- Phthisis, on the infrequency of, in marshy districts, 287.
- Physician practising as an apothecary, 91; note from Mr. F. G. Reed, 127.
- Pickford, Dr. on conical cornea, 690.
- Placenta, retained, Mr. Moyle on a case of, succeeded by fatal hemorrhage, 17.
- Plague, on the destruction of the contagion of the, 496.
- Pneumonia, Mr. Jo'm Christie's case of, complicated with pleuritis, 338.
- Pneumonia, congestive, Mr. Erichsen on, consequent upon surgical operations, diseases, and injuries, 154.
- Pneumo-thorax, clinical lecture, by Dr. Barker, on a case of, 161.
- Pneumo-thorax, Dr. H. M. Hughes's essay on:—Change of opinion respecting this complaint, 435; opinions of recent writers, 434; causes of pneumo-thorax, 436; symptoms, 437; physical signs, 438; theory of the difference of symptoms and physical signs of pneumo-thorax, 439; diagnosis, 465; prognosis and treatment, 466; cases, 468 to 501, 529 to 531; concluding remarks, 533; conclusions, 535.
- Poisoning by sulphate of potass, Mr. G. M. Mowbray on, 54.
- Poisoning by sulphate of potass, remarks on, by a drug-vendor, 154.
- Poisoning by the bichromate of potash, Mr. Wilson's case of, 734.
- Poor, increase of disease among the, 317.
- Posthumous extracts from the veterinary records of the late John Field, 621.
- Practice, editorial remarks on the progressive changes in, 250.
- Pregnancy, crocodile in the vomiting of, 784.
- Prescriber's pharmacopœia, the, reviewed, 83.
- Proctor, Mr. A. G. on a case of acute bronchitis, 213; correction of an error in the report of the case, 513.
- Professional etiquette, breach of, 255.
- Pyroligneous acid, Dr. Furnivall on the employment of, in tinea capitis, 16.
- Quack advertisements, note from Dr. Ranking respecting the insertion of, on the covers of the medical journals, 553.
- Quackery, editorial observations on the prevalence of, 120.
- Qualification for general practice, 126.
- R.
- Raciborski, M. on the influence of menstruation on the secretion of milk, 639.
- Radiis, Mr. Lonsdale on the diagnosis of fractures of the lower end of the, 107.
- Rankin, Dr. on cholera, 213, 331.
- Ranking, Dr. on quack advertisements, 553.
- Reade, Rev. J. B. on a new process for cleaning glasses previous to mounting, 639.
- Reid, Dr. William, on the new form of fever at present prevalent in Scotland, 358.
- Reinsch, Professor, on a new mode for the detection of arsenic, 31.
- Results of operations, remarks by T. H. B., 876.
- Rheumatism in the horse, 672; Mr. Monday on a case of, 783.
- Rickets, Dr. J. R. Smyth on, 326.
- Ritchie's, Dr. contributions to the physiology of the human ovary, 562, 652, 737, 793, 854.
- Robinson's, Mr. remarks on flooding from the uterus, 81.
- Robinson, Mr. G. on the blood and urine, 151; on a peculiar affection occasioning loss of the eyebrows, 619.
- Ros-ignon, M. on the existence of copper in organic tissues, 237.
- Royal Medical and Chirurgical Society, papers read at the:—
- Mr. Stanley's two cases of rupture of the ureter, or pelvis of the kidney, from external violence, followed by large effusion of urine into the abdomen, 253.
- Dr. Seymour on two cases of ulcer of the stomach, producing circumscribed abscesses in the peritoneum, 254.
- Mr. Dalrymple on the cause of the occasional presence of spermatozoa in the fluid drawn from the sac of common hydrocele, 315.
- Mr. Caesar Hawkins's cases of carcinoma of the thyroid gland, 315.
- Mr. Drewry Otley on cysticercus cellulosa of the brain, 316.
- Dr. Bence Jones on the state in which uric acid exists in the urine, 317.
- Mr. B. Cooper on a case of alarming syncope from the admission of air into a vein during an amputation of the shoulder joint, 376.
- Case of the removal of a diseased ovary, terminating fatally on the seventh day after the operation, 524.
- Mr. B. Cooper's case of extirpation of an ovarian cyst, 524.
- Dr. Mayo on a case of phlegmasia dolens and synovitis, 581.

Q.

- Mr. Erasmus Wilson's case in which a horn was developed from the human skin, 581.
- Dr. George Burrow's case of extensive carcinoma of the lungs, 697.
- Dr. Bostock on the effect of water drinking in the cure of gout, 698.
- Dr. J. A. Wilson's account of certain acute diseases in the throat and larynx, one of which was cured by tracheotomy, 776.
- The president's address on occasion of the anniversary meeting, 777.
- List of officers and other members of the council for the year 1844-45, 780.
- Mr. Dalrymple on the early organization of coagula and mixed fibrinous effusions, under certain conditions of the system, 844.
- Dr. Davy on the composition of the mercurium, 844.
- Mr. T. W. King's account of a specimen of partial fracture of the neck of the thigh-bone, 846.
- Dr. Webster on the influence of the weather on disease, 846.
- Royal General Dispensary, Dr. J. B. Thompson appointed physician to, 816.
- Rumsey, Mr. of Gloucester, notice of the death of, 256.
- S.
- Saffron, spurious, how to distinguish, 528.
- Salary, multifidens, note from Dr. J. C. Badeley, 432.
- Salivary glands in animals, M. Budge on the extirpation of, 64.
- Salts of iron, double, Mr. Hemingway on the, 338, 359.
- Scirrhus, Dr. Frick on the cure of, by iodine, 816.
- Scirrhus tumor of the female breast, Sir B. C. Brodie on cases in which it is expedient to perform the operation for the removal of, 628, 664.
- Schlegel's, M. essay on the physiognomy of serpents, reviewed, 454.
- Scott, Dr. on the employment of the infusion of matico in leucorrhœa, 113.
- Scott's, Mr. John, work on cataract, reviewed, 548.
- Scoutetten's, M. case of tracheotomy in the last stage of croup, 750.
- Secrets of a union workhouse, 627.
- Segalas, M. on a remarkable case of calculus, 319.
- Seminal discharges, Dr. Allnatt on, and on the influence of creosote in mucous and sanguinous discharges from the urethra, 18.
- Seymour, Dr. on two cases of ulcer of the stomach, producing circumscribed abscesses in the peritonæum, 254.
- Sharkey, Dr. on the employment of digitalis in epilepsy, 305.
- Sheffield, vital statistics of, 62, 121.
- Sherwin, Mr. H. C. on the hydropathic treatment of gout, 806; fungoid disease of the uterus, 807.
- Shipman's, Dr. account of the effects of a large dose of arsenic, taken by a lunatic, 877.
- Sick poor in Scotland, Mr. Joseph Bell on the neglect of the, 780.
- Simpson's, Mr. description of a new instrument for crushing large calculi in the bladder, 875.
- Sir James Graham's medical reform bill, 844.
- Smith's, Dr. E. account of a singular case of malformation of the sexual organs, with absence of the urethra, 174.
- Smith's, Dr. W. case of phlegmonous erysipelas treated by acetate of lead and opium, 764.
- Smith, Dr. J. M. on the influence of opium upon the catamenial functions, 876.
- Society for the relief of widows and orphans of medical men, some particulars respecting the formation of the, 664; account of the annual dinner, 697.
- Soltan's, Dr. case of delirium tremens, 274.
- Southam's, Mr. case of removal of a dropsical ovary, 198, 236.
- Spasm of the glottis, Dr. Allnatt on a case of, 273.
- Spermatozoa, Mr. Lloyd on the presence of, in the fluid of hydrocele, 181; Mr. Dalrymple on the cause of the occasional presence of, in the fluid drawn from the sac of common hydrocele of the tunica vaginalis, 345.
- Spermatic artery, Mr. T. B. Curling on ligature of the, 313.
- Spina bifida, case of, treated successfully by repeated punctures, 527.
- Spleen, on the function of the, 840.
- Spurious saffron, how to distinguish, 528.
- St. George's Hospital, result of the election for assistant-surgeon to, 375.
- Stafford, Mr. R. A. on irritation, and irritative or surgical fever, 817.
- Stallard's, Mr. midwifery case, 212.
- Stanley's, Mr. account of two cases of rupture of the ureter or pelvis of the kidney, from external violence, followed by large effusion of urine into the abdomen, 253.
- Starr's, Dr. case in which urine escaped at the umbilicus, 484.
- Statistics of insanity in France, 221.
- Statistics of the Royal College of Physicians, 342; remarks on the, by a Licentiate, 432.
- Statistics in midwifery, by Dr. Metcalf, 526, 638.
- Stomach, Mr. T. W. King on the part of the, which digests, and the sources of hæmoptysis, 175.

Strangulated intestines, cases of, from rotation of the sigmoid flexures, 430.
 Strangulated hernia, Mr. Walker on the good effects of opium in, 484.
 Stricture of the trachea, 223.
 Stricture of the urethra, Mr. B. Phillips on the treatment of, 257; on the consequences of, 321; Mr. J. F. France on the medical treatment of, 593.
 Strychnine, Dr. Gilbert on the employment of, in influenza, 703.
 Students, a few words to, 58.
 Sulphate of potass, Mr. G. M. Mowbray on poisoning by, 54; on the action of, 114; remarks on poisoning with, by a drug-vendor, 124.
 Suppression of urine, additional remarks on, by Dr. J. C. Hall, 683.
 Surgeons of the Liverpool Northern Hospital, reply by the, to a paper by Mr. J. P. Halton, on the results of operations, 645.
 Surgical instruments, caution respecting the quality of, 525.
 Sydenham Society, suggestion by a member to the council, 64.
 Syphilis, secondary, Mr. B. Phillips' clinical lecture on, 193.
 Syphilis, inveterate, efficacy of arsenic in a case of, 224.
 Syphilis, Sir B. C. Brodie on the administration of mercury in, 665.

F.

Tartar emetic recommended by Dr. Gilbert in cases of tardy labour, 815.
 Taunton and Somerset Hospital, reply to a complaint as to the low remuneration offered in an advertisement for house-surgeon to the, 524; Dr. Badeley's reply, 565.
 Teaching and learning, editorial observations on, 183.
 Thigh-bone, Mr. T. W. King's account of a specimen of partial fracture of the, 846.
 Thompson, Dr. Theophilus, on ischuria renalis, 478.
 Thompson's, Dr. J. B. case of ergotism, 512; medical notes, 542.
 Thompson, Dr. J. B. appointed physician to the Royal General Dispensary, 816.
 Tice's, Dr. case of bronchial calculus, with observations on disease of the bronchial glands, 153.
 Tinea capitis. Dr. Furnivall on the employment of pyroligneous acid in, 16.
 Toothache, Queen Elizabeth suffering from the, 351; Dr. Stanelli on the employment of chloride of zinc in, 672.
 Trachea, stricture of the, 223.
 Tracheotomy, M. Scoutetten's case of, in the last stage of croup, 750.

Travers, Mr. on the physiology of inflammation, reviewed, 452.
 Tripe's, Mr. cases of pulmonary empysema as a cause of death, 247.

U.

Ulcer of the stomach, Dr. Seymour on two cases of, producing circumscribed abscesses in the peritoneum, 254.
 Ulceration of the internal jugular vein, communicating with an abscess, Mr. Bloxam's case of, 176.
 Ulceration of the pulmonary artery, Mr. Dalrymple on a case of, 178.
 Unhealthiness of Liverpool, editorial observations on the, 88.
 Unhealthiness of parts of the metropolis, 128.
 Union workhouse, secrets of a, 627.
 University of London, examinations at, for the degree of M.B., 186; second examination, 256; names of gentlemen who passed, 256; examination for the degree of doctor of medicine, 348; candidates on whom the degree has been conferred, 350.
 Ureter, Mr. Stanley on two cases of rupture of the, from external violence, followed by large effusion of urine into the abdomen, 253.
 Ureter, case of neuralgia of the, 590.
 Urethra, Mr. Harding's case of calculus in the, 808.
 Uterus, Mr. H. C. Sherwin on fungoid disease of the, 806.
 Urethra, Mr. B. Phillips on stricture of the, 257; on the consequences of, 321.
 Urethra, Mr. J. F. France on the medical treatment of stricture of the, 593.
 Urine, fatty, Dr. Golding Bird's remarks on, 110; on the respective value of the different tests proposed for the detection of a diabetic state of the urine, 243.
 Urine, Dr. Starr on a case in which it escaped at the umbilicus, 484.
 Urine, Dr. J. C. Hall on suppression of, 683.
 Urine, milky, Dr. T. Ogier Ward on a case of, 736.
 Uterus, Mr. Heath's case of excision of the, by the abdominal section, 309.
 Uterus, Mr. R. D. Grainger on the nerves of the, 341.
 Uterus, Dr. Robert Lee on the nerves of the, 483.
 Uterus, Dr. Bowen's case of rupture of the, in a woman who had twice undergone the Cæsarean operation, 491.

V.

- Van Oye, Dr. account of a curious conifer-void animal observed by, 496.
- Veilbach, Dr. Granville on the water of, 495.
- Velpéau, M. on the circumstances which should regulate the various modes of employing the nitrate of silver in ophthalmia, 63.
- Vibratile cilia, best mode of examining the form, structure, and movements of, 815.
- Villi, intestinal, MM. Delafond and Gruby on the structure and function of the, 126.
- Vital statistics of Sheffield, 62, 121.
- Vivisection, Mr. Macilwain on, 30, 188; Dr. Robert Hull on, 55, 219; Dr. Glover on, 31.
- Vomiting in pregnancy, creosote recommended by Dr. Pitschaft for, 784.
- Webster's, Dr. case of paralysis, without loss of sensation, from disease of the cervical medulla, 151.
- Webster, Dr. on the influence of the weather on disease, 846.
- Weekes's, Mr. treatise on the warm water remedy, reviewed, 455.
- West of London Institute for Diseases of the Eye, 429.
